THE
PRACTICE
OF
MEDICINE

TEXT-BOOK FOR PRACTITIONERS AND STUDENTS
WITH SPECIAL REFERENCE TO DIAG-
NOSIS AND TREATMENT

BY

JAMES TYSON, M.D.

PROFESSOR OF MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA AND PHYSICIAN TO THE HOSPITAL
OF THE UNIVERSITY; PHYSICIAN TO THE PENNSYLVANIA HOSPITAL; FELLOW OF
THE COLLEGE OF PHYSICIANS OF PHILADELPHIA; MEMBER OF THE
ASSOCIATION OF AMERICAN PHYSICIANS, ETC.

THIRD EDITION
THOROUGHLY REVISED AND IN-PARTS REWRITTEN

With 134 Illustrations

INCLUDING COLORED PLATES

PREFACE TO THE FIRST EDITION.

I HAVE no apology to make for preparing this book. I have long contemplated it, and have finished it after several years' labor. It has taken some time, because it represents almost purely personal work, which has been frequently interrupted. It does not pretend to be based on my personal practice only. In these days of specialized work this would be impossible, though with most of even the rare forms of disease in every section I have had some experience. To fill in the gaps of my own knowledge I have used that of others, but have always sought to make suitable acknowledgment to the proper source, and if this has not been done in any case, it has been a matter of oversight.

I had not, at the outset, expected to illustrate the work, but, as it progressed, a certain number of illustrations seemed necessary, not only to explain the text, but also, in a few instances, to render clearer the treatment described. Thus the number of charts and other drawings has grown to nearly a hundred, all of which, it is hoped, will be found useful. In expectation of the ultimate adoption of the metric system for the measuring of doses, these have been indicated throughout the book in the metric and English measures.

Acknowledgment is due to Dr. Joseph P. Walsh and Mr. M. A. Morin for suggestions after reading the text, to Dr. William Schleif for material assistance in Section XV, and to my son, Dr T. Mellor Tyson, for assistance throughout the work and especially in preparing the index.

1506 SPRUCE ST., PHILADELPHIA, *October 1, 1896.*

PREFACE TO THE THIRD EDITION.

IN preparing the third edition of the Text-Book of Medicine, I have sought to make its contents represent, as far as possible, the present state of modern medicine. The subject is an extensive one and it may be that some important points have escaped notice, and I will be indebted to readers who may call my attention to them.

It is not easy to point out the sections in which additions and changes have been most numerous, but as the infectious diseases are those of which our knowledge is being most enlarged and modified, a good many alterations and additions will be found in the pages devoted to them. So numerous have they been in all parts that the entire book has been reset.

I have again had the advantage of a careful revision of the Section on Nervous Diseases by Dr. W. G. Spiller and I believe it will be found fully abreast of the times. The subject of Dysentery has been carefully revised and partly rewritten by my colleague, Dr. Simon Flexner, whose studies on this subject have made him an acknowledged authority.

I have had much valuable assistance from my son, Dr. T. Mellor Tyson, in various ways.

1506 SPRUCE ST., PHILADELPHIA, *September, 1903.*

CONTENTS

SECTION I.

INFECTIOUS DISEASES.

	PAGE		PAGE
Typhoid Fever,	17	Croupous Pneumonia,	212
Paratyphoid Fever,	54	Bronchopneumonia,	228
Mountain Fever,	54	Chronic Interstitial Pneumonia,	233
Typhus Fever,	55	Embolic Pneumonia,	235
Relapsing Fever,	59	Embolic Non-septic Pneumonia,	235
Malta Fever,	63	Embolic Septic Pneumonia,	237
The Malarial Fevers,	65	Tuberculosis,	238
Clinical Varieties,	73	I. General Etiology and Invasion,	
Intermittent Fever,	73	Morbid Anatomy,	238
Remittent Fever — Estivo- tumnal Fever,	76	II. Acute Tuberculosis,	244
Pernicious Malarial Fever—The Congestive Chill,	77	1. General or Typhoid Form,	245
Irregular Forms of Malarial Fever,	78	2. Pulmonary Form,	247
Malarial Hematuria or Hemo- globinuria or Intermittent Hematuria—Blackwater Fever, Malarial Cachexia or Chronic Malaria,	79	3. Meningeal Form. Tubercu- lous Meningitis,	249
Yellow Fever,	83	III. Chronic Tuberculosis,	252
Dengue,	90	Pulmonary Tuberculosis,	252
Cholera,	91	Chronic Ulcerative Phthisis,	254
Dysentery,	104	Fibroid Phthisis,	265
Acute Catarrhal Dysentery,	104	Treatment of Tubercular Phthisis,	266
Amebic or Tropical Dysentery,	109	IV. Tuberculosis of Lymphatic Glands,	279
Bacillary Dysentery,	106	V. General Tuberculosis of the Serous Membranes,	281
Chronic Dysentery,	113	Tuberculosis of the Pleura,	281
The Plague,	114	Tuberculosis of the Perito- neum,	282
Measles,	118	VI. Tuberculosis of the Genito- urinary Organs,	283
Rubella,	122	Tuberculosis of the Kidney,	283
Scarlet Fever,	124	Tuberculosis of the Pelvis of the Kidney, Ureters, and Bladder,	284
Diphtheria,	132	Tuberculosis of the Ovaries, Fallopian Tubes, and Uterus,	285
Smallpox,	145	Tuberculosis of the Testes, Prostate Gland, and Seminal Vesicles,	285
Vaccine Disease,	152	VII. Tuberculosis of the Mam- mary Glands,	286
Chicken-pox,	156	VIII. Tuberculosis of the Heart and Blood-vessels,	286
Whooping-cough,	157	Leprosy,	287
Mumps,	161	Rheumatic Fever,	289
Influenza,	162	Infectious Diseases of Doubtful Na- ture,	297
Cerebrospinal Fever,	167	Ephemeral Fever—Febricula,	297
Erysipelas,	177	Protracted Simple Continued Fe- ver,	298
Septicemia and Pyemia,	181	Weil's Disease,	300
Hydrophobia,	184	Miliary Fever,	301
Tetanus,	190	Glandular Fever,	302
Anthrax,	194		
Glanders and Farcy,	197		
Actinomycosis,	198		
Foot and Mouth Disease,	200		
Milk Sickness,	201		
Syphilis,	202		
The Gonorrhœal Infection,	210		
Gonorrhœal Arthritis,	210		

SECTION II.

DISEASES OF THE DIGESTIVE SYSTEM.

	PAGE		PAGE
Diseases of the Mouth,	304	Diseases of the Intestines,	378
The Coated Tongue,	304	Simple Acute Catarrhal Enteritis,	378
Derangement Due to Dentition,	304	Chronic Catarrhal Enteritis,	382
Stomatitis,	306	Cholera Morbus,	384
Simple Acute Catarrhal Stoma- titis,	306	Diarrheas of Children,	386
Apthous Stomatitis	307	Acute Dyspeptic Diarrhea,	386
Mycotic Stomatitis,	307	Acute Entero-colitis,	388
Ulcerative Stomatitis,	308	Cholera Infantum,	389
Treatment of Different Forms of Stomatitis,	310	The Celiac Affection in Children,	391
Cancrum Oris,	311	Pseudo-membranous Enteritis,	392
Glossitis,	311	Phlegmonous Enteritis,	392
Glossitis Desiccans,	312	Hemorrhagic Infarct of the Bowel,	392
Eczema of the Tongue,	312	Ulceration of the Bowel,	393
Leukoplakia Buccalis,	312	Tubercular Ulcer,	393
Mucous Patches,	313	Embolio Ulcer,	394
Diseases of the Salivary Glands,	313	Syphilitic Ulcer,	394
Functional Derangements,	313	Appendicitis,	394
Inflammation of the Salivary Glands,	313	Recurring and Relapsing Appen- dicitis — Chronic Appendicitis,	404
Angina Ludovici,	314	Intestinal Obstruction,	409
Diseases of the Tonsils and Pharynx,	315	I. Internal Strangulation,	409
Quinsy,	315	II. Intussusception — Invagina- tion,	410
Follicular Tonsillitis,	316	III. Twists and Knots—Volvu- lus,	411
Chronic Tonsillitis and Hyper- trophly of the Adenoid Tissue of the Pharynx,	317	IV. Obstruction by Abnormal Contents or Foreign Bodies,	411
Simple Circulatory Derangements of the Pharynx,	320	V. Strictures and Morbid Growths,	412
Acute Catarrhal Pharyngitis,	320	VI. Fecal Obstruction,	412
Chronic Catarrhal Pharyngitis,	321	Constipation,	420
Ulceration of the Pharynx,	322	Dilatation of the Colon,	422
Phlegmonous Pharyngitis,	322	Nervous Affections of the Bowel,	424
Postpharyngeal Abscess,	323	I. Derangements of Motion,	424
Diseases of the Esophagus,	323	II. Derangements of Sensibil- ity,	425
Exploration of the Esophagus with the Bougie,	323	III. Secretion Neuroses,	427
Esophagitis,	324	Carcinoma of the Bowel,	428
Spasm of the Esophagus,	324	Hemorrhoids,	431
Cancer of the Esophagus,	325	Diseases of the Liver,	435
Stricture of the Esophagus,	326	Abnormalities in the Shape and Position of the Liver,	435
Dilatation of the Esophagus,	326	Diseases of the Bile Passages and Gall-bladder,	436
Diseases of the Stomach,	329	Jaundice, or Icterus,	436
Diagnostic Technique,	329	Icterus Neonatorum,	439
External Examination,	329	Simple Catarrhal Jaundice,	439
Internal Examination or Chem- ical Examination of Gastric Contents,	332	Cholelithiasis,	441
Acute Catarrhal Gastritis,	342	Acute Impaction,	443
Chronic Catarrhal Gastritis,	343	Chronic Impacted,	444
Phlegmonous or Suppurative Gastritis,	349	Acute Infections,	448
Traumatic and Toxic Gastritis,	349	Cancer of the Gall-bladder,	450
Diphtheritic Gastritis,	350	Carcinoma,	451
Mycotic Gastritis,	350	Stenosis,	451
Nervous Dyspepsia,	350	Cicatrical Contraction,	452
Atonic Dyspepsia,	352	Parasites,	452
Gastralgia,	353	Diseases of the Blood-vessels of the Liver,	452
Hyperchlorhydria,	354	Hyperemia,	452
Anorexia Nervosa,	357	Passive Hyperemia—Red At- rophy,	452
Nervous Vomiting,	357	Active Hyperemia,	454
Gastric and Duodenal Ulcers,	359	Thrombosis and Embolism,	454
Cancer of the Stomach,	366	Pylethrombosis,	454
Dilatation of the Stomach,	373	Pylephlebitis,	455
Visceroptosis,	376		

	PAGE		PAGE
Diseases of the Blood-vessels of the Liver:		Diseases of the Pancreas:	
Fatty Liver,	455	Cancer of the Pancreas,	483
Fatty Infiltration,	456	Sarcoma of the Pancreas,	484
Fatty Metamorphosis,	457	Cysts of the Pancreas,	484
The Amyloid Liver,	457	Pancreatic Cellulitis,	485
Cirrhosis of the Liver,	458	Diseases of the Spleen,	485
Suppurative Hepatitis,	465	Splinitis,	485
Perihepatitis,	468	Perisplenitis,	485
Glissonian Cirrhosis,	469	Abscess of the Spleen,	485
Acute Yellow Atrophy of the Liver,	469	Rupture of the Spleen,	485
Morbid Growths of the Liver,	471	The Amyloid Spleen,	486
Carcinoma of the Liver,	471	Atrophy of the Spleen,	486
Sarcoma,	471	Hemorrhagic Infarct of the Spleen,	486
Syphilis of the Liver,	475	Neoplasms of the Spleen,	486
Parasites of the Liver,	477	Echinococcus of the Spleen,	486
Echinococcus Disease or Hydatid Cyst of the Liver,	477	Wandering Spleen,	486
Other Parasites of the Liver,	481	Diseases of the Peritoneum,	487
Diseases of the Pancreas,	481	Acute Peritonitis,	487
Acute Pancreatitis,	482	Chronic Peritonitis,	491
Chronic Pancreatitis,	483	Local, Circumscribed, or Chronic Adhesive Peritonitis,	491
		Diffuse Chronic Peritonitis,	492
		Cancer of the Peritoneum,	492
		Ascites,	493

SECTION III.

DISEASES OF THE RESPIRATORY SYSTEM.

	PAGE		PAGE
Diseases of the Nose,	497	Diseases of the Trachea and Bronchial Tubes:	
Rhinitis,	497	Bronchial Asthma,	526
Chronic Nasal Catarrh,	498	Plastic or Fibrinous Bronchitis,	530
Hay-fever,	501	Diseases of the Lungs,	531
Diseases of the Larynx,	503	Emphysema,	531
Examination of the Larynx,	503	Vesicular Emphysema—Pseudo-hypertrophic Emphysema,	532
Acute Catarrhal Laryngitis,	505	Tumors of the Lung,	537
Spasmodic, Catarrhal, or False, Croup,	506	Diseases of the Pleura,	539
Simple Chronic Catarrhal Laryngitis,	508	Acute Pleurisy,	539
Tubercular Laryngitis,	511	Chronic Pleurisy,	547
Syphilitic Laryngitis,	513	Hydrothorax and Hematothorax,	548
Edema of the Glottis,	513	Pneumothorax,	549
Paralysis of the Laryngeal Muscles,	514	Morbid Growths of the Pleura,	551
Diseases of the Trachea and Bronchial Tubes,	517	Mediastinal Disease,	551
Acute Bronchitis,	517	Mediastinal Tumors,	553
Chronic Bronchitis,	519	Mediastinal Abscess,	556
Bronchiectasis, or Bronchial Dilatation,	524	Simple Lymphadenitis,	557

SECTION IV.

DISEASES OF THE HEART AND BLOOD-VESSELS.

	PAGE		PAGE
General Symptomatology of Cardiac Disease,	558	Diseases of the Endocardium,	567

PRACTICE OF MEDICINE.

SECTION I.

INFECTIOUS DISEASES.

TYPHOID FEVER.

SYNONYMS.—*Typhus abdominalis*; *Enteric Fever*; *Pythogenic Fever*; *Gastro-enteric Fever*; *Nervous Fever*; *Autumnal Fever*; *Slow Nervous Fever*.

Definition.—Typhoid fever is an acute infectious fever due to the implantation and proliferation of the typhoid bacillus—the bacillus of Eberth. It is especially characterized anatomically by hyperplastic and ulcerative lesions of the lymph-follicles of the intestine, of the mesenteric glands, and by enlargement of the spleen.

Historical.—The disease is probably coeval with civilization, and is easily recognizable in the descriptions of Hippocrates (B. C. 460–357) and Galen (A. D. 130–200); and in more modern times in those of Adrianus Spigelius (1624), Thomas Willis (1659), N. Hoffmann (1699), Thomas Sydenham (1685), and others in the seventeenth century and in the next. Noteworthy are the writings of E. Gilchrist (1734), John Huxham (1739), J. C. Riedel (1748), and R. Manningham (1746). Doubtless Huxham's "slow nervous fever," described in his "Essays on Fevers," was the typhoid of the present day, and his "putrid malignant" the rarer typhus of to-day. But Huxham regarded typhoid as a variety of continued fever rather than as a distinct and separate fever, and it was not until 1813 that Pierre Bretonneau, of Tours, described it under the name *douthiéntéritie* and Petit and Serres as *fièvre entero-mésentérique*. It was, however, the writings and teachings of the great French physician, Louis, which did most to disseminate a knowledge of the true nature of typhoid fever—to which he gave the name it bears. His great work was published in 1829.* Among his pupils, who came from every country, was a coterie of brilliant young Americans, including William W. Gerhard and C. W. Pennock, of Philadelphia, and James Jackson, Jr., of Boston. The first, after his return to America, had the opportunity, in conjunction with Pennock, of studying the disease in the wards of the Philadelphia Hospital in the spring and summer of 1836, and of contrasting it with typhus fever, of which there was an epidemic then prevalent in Philadelphia. These two observers were the first to point out the difference between the two diseases. This they did in the "American Journal of the Medical Sciences" in 1837. Their publications were followed in 1838 by a paper by James Jackson, Sr., entitled "Report on Typhoid Fever," and another by Enoch Hale "On the Typhoid Fever of New England," which probably had their impulse in the information furnished by the younger Jackson to his father on his return from Paris. Thus it came to pass that Elisha Bartlett's work on the "Diagnosis and Treatment of Typhus and Typhoid Fevers," an American text-book published in 1842, contained the first separate description of the diseases. For up to 1838 only typhoid fever was known in Paris. At this time Alfred Stillé, who had been the house physician of Gerhard and Pennock in the Philadelphia Hospital, and had learned there the distinctive features of typhus and typhoid, went to Paris, and in 1838 read a paper before the Société Médicale d'Observation pointing out the differences between them. George C. Shattuck had been similarly trained in Boston, and contributed a paper to the same society. Shattuck also went to London at Louis' request, and at the Fever Hospital there saw the two distinct affections, on which he reported to the Society on his return to Paris.† He insisted on the existence of two fevers in England

* Louis, P. C. A., "Recherch. anatom., patholog., et thérapeutiques sur la maladie connue sous les noms gastro-entérite, fièvre putride," etc., Paris, 1829.

† "Amer. Med. Examiner," February 1, March, 1840.

In Germany, J. V. Hildenbrand had pointed out differences between typhoid and typhus as early as 1810, but also regarded them as varieties of the same disease, and not distinct diseases. These views were maintained for many years in Germany, but since 1859, at least, correct notions have prevailed. In Great Britain, in 1835, Peebles, of Glasgow, who had observed the rubeoloid eruption in the contagious typhus of Italy, pointed it out to Drs. R. Perry and A. P. Stewart. The former, according to Stewart, was the first to contend for the difference between the eruptions of typhus and typhoid. His writings, as quoted by Murchison, do not show this. Stewart, however, separated the two affections in a paper published in 1840.* In England it was not until 1849-51 that Sir William Jenner, † by his experiments and observations, clearly demonstrated their difference, and about the same time definite ideas were arrived at in France. Since 1850 the two diseases have been everywhere recognized and described as distinct and separate, except in Germany, where the recognition came a few years later. ‡

Etiology.—The *bacillus typhosus*, to which prevailing views ascribe typhoid fever, was discovered by Eberth in 1880 in the intestine of a case of the disease. This observation was promptly confirmed by Klebs, Eppinger, Koch, v. Meyer, Friedländer, Gaffky, and others, who found it in the intestines, lymphatic system including the mesenteric glands and spleen, in the liver and the kidneys, the blood and bone-marrow, and even in bile and urine, as well as in the rose-colored spots. It was secured in pure culture from the spleen and infected lymphatic glands by Gaffky in 1884. The bacillus is described as a short, rod-like bacterium, whose length is three micromillimeters, breadth one micromillimeter. Thus its length is about one-third the diameter of a red blood-disc, and its width one-ninth of the same, though its size and shape vary somewhat with the culture-medium and the age of the bacillus. Its ends are rounded, and sometimes there can be seen toward them, dark, glistening, round bodies. These were at one time believed to be spores, but recently this germ has been classed among those that do not produce spores. §

Early observations have been rendered somewhat unreliable by the very close resemblance of this bacterium to the bacterium coli. Several methods, all more or less successful, have superseded that suggested by Elsner || for differentiating the two bacilli.

The bacillus stains readily in a saturated watery solution of methylene-blue. Cultures may be made from the fecal discharges on the tenth day of the disease or later, but with difficulty, and are often negative; probably because the bacilli are not numerous. E. Fränkel and M. Simmonds ¶ early injected pure cultures of the typhoid fever bacillus into the blood of mice, rabbits, and guinea-pigs, with fatal results, which are now ascribed to toxins thus introduced. By introducing the cultures into the duodenum, Klemperer, Levy, and others caused lesions similar to those of typhoid fever, though more recently similar intestinal lesions have been produced by other bacteria, including the bacterium coli commune.

The resisting powers of the typhoid bacillus are very great. It thrives at room-temperature. The thermal death-point is given by Sternberg at 156° F. (69° C.). According to Klemperer and Levy, the bacilli remain vital for three months in distilled water, though in ordinary water the commoner and more vigorous saprophytes consume them. When buried in the upper layers of the soil, they retain their vitality for nearly six months. Cold

¶ Von Jaksch, "Klinische Diagnostik," 1892, S. 213.

has no effect upon them, for repeated freezing and thawing fail to kill them. They have lived upon linen for from sixty to seventy-two days, and on buckskin from eighty to eighty-five days. Sternberg has succeeded in keeping alive hermetically sealed bouillon cultures for more than one year. John S. Billings and Adelaide Ward Peckham, in some experiments in the Laboratory of Hygiene, University of Pennsylvania, dried bouillon cultures on threads and found that typhoid bacilli lived in a vacuum two hundred and seven days; in a desiccator over sulphuric acid, two hundred and three days; in a closet, two hundred and twenty-eight days, and proved more resistant than the bacillus coli communis or staphylococcus aureus. One-tenth to 0.2 of one per cent. carbolic acid added to a culture-medium is without effect upon the growth of the bacillus; 0.5 of one per cent. strength of carbolic acid and 0.05 of one per cent. corrosive sublimate solutions are, however, fatal to it. Of all agents except high heat, sunlight seems to be among the most powerful to destroy it. The experiments of Billings and Peckham,* just alluded to, go to show that insolation for two hours destroys 98 per cent. of the germs, and in three to six hours kills all. This very important observation, made first by Janowski in 1890,† has been confirmed by Dieu-donné.‡

L. Brieger announced in 1885 that the pathogenic action of the typhoid bacillus was due to a specific product of the bacillus, a soluble toxin, but later studies led by R. Pfeiffer have shown that these bacteria do not yield a soluble toxin, but store up the poison in their bodies, whence it goes over in very small quantities into the fluids in which the bacilli are cultivated.

The bacillus itself most frequently enters the blood through the stomach in drinking-water or milk, in both of which it has been found during epidemics. There is reason to believe also that it may be inhaled. It has been found in water-filters by Harold C. Ernest and T. M. Prudden. It is quite well settled that the bacilli find their way into food and drink through the careless disposition of alvine discharges from typhoid fever patients, and more than likely that food may be contaminated by contagion conveyed from these discharges by the common house-fly. An oyster bed may be infected by sewage; green vegetables, by polluted water sprinkled upon them.

Whether the bacilli multiply outside the body in the water of wells or rivers to which they have obtained access is not well settled, but, judging from the large number of persons sometimes infected from those sources, it is not unreasonable to conclude that such multiplication can take place. A most noteworthy instance was the epidemic of 1885 at Plymouth, Penna., U. S. A., where 1200 persons were attacked and 130 died, all the cases starting from a single subject, whose discharges contaminated the water-supply. The recent epidemic (1897) at Maidstone, England, furnishes another illustration of the effect of contaminated water-supply. Within two weeks after the outbreak, about the middle of September, 509 cases were reported; by October 27, 1748 cases; November 17, 1848 cases; in all, about 1900 in a population of 35,000. The bacilli develop rapidly in milk and in the soil. The relatively infrequent communication of typhoid fever to physicians, nurses, and others in close communication with the disease is explained by the fact that the contagion escapes from the patient in the

* "Influences of Certain Agents in Destroying the Vitality of the Typhoid and Colon Bacillus," "Science," February 15, 1895.

† "Zur Biologie des Typhus-Bacillus," "Centralbl. f. Bakteriol.," viii., 1890.

‡ "Beitrage zur Beurtheilung der Einwirkung des Lichtes auf Bacterien," "Arbeiten aus dem kaiserlichen Gesundheitsamte," Band ix., S. 405, 1894.

stools alone, and as these are commonly promptly disposed of, the chances for the dissemination of the poison are correspondingly few. Carelessness in the disposition of these discharges, as the result of which they are allowed to dry on linen, whence the bacilli pass into the air of the room, does sometimes occasion the infection of nurses and physicians and others attending on typhoid cases. The inadvertent drinking of water from a bath used in tubbing typhoid fever cases is said to have caused the disease in a nurse.

Predisposing Causes.—Experience fails to establish definite predisposing causes of typhoid fever, but new-comers are more likely to be attacked than old residents, as early shown by the French physicians in Paris. It certainly often attacks the strong and healthy as fiercely as the feeble and delicate, while allowance must be made for the more frequent exposure of the healthy. Thus caused, typhoid fever is unlimited in its distribution by climate or civilization, but it may be complicated by disease peculiar to certain localities, pre-eminently malaria.

Typhoid fever is a disease of adolescents and adults under thirty, although it may occur at any age. Less common in children, perforation has been found in a child five days old, while not a few cases have been reported in sucklings. Infection *in utero* is claimed as possible because of successful cultures of bacilli from the fetus. In the young the duration of the disease is short and the prognosis singularly favorable. It has occurred at the age of seventy-five, eighty-six, and even ninety. More men than women have typhoid fever (71 per cent. of 444 cases collected by Reginald H. Fitz), probably because of their more frequent exposure. The assertion that the pregnant state seems to protect against typhoid fever is not substantiated by experience in Philadelphia, in evidence of which I may state that within two months there were received in my wards at the Hospital of the University of Pennsylvania three pregnant women with typhoid fever.

Typhoid fever is more common in the late summer and autumn months than at any other time of the year, whence one of the names, "autumnal fever." Heat has probably to do with the ripening of the cause, but the relation of moisture to such maturing is not so well settled. It has, however, been observed that hot and dry summers are followed by more cases than hot and moist summers. Buhl and Pettenkofer have shown that more cases succeed seasons when the ground water is low—that is, when the springs are low and the upper layers of the soil comparatively dry—than when the ground water is high and the soil is saturated with moisture to a point nearer to the surface. Under the latter condition of high ground water the germs are retained *in situ*. When the ground water is low, on the other hand, the constant circulation between the air in the loose soil and that above it conveys the germs upward, and they pervade the air accordingly. The hot and dry summer furnishes identical conditions. While it is not impossible that the germs may be transmitted through the air, and the disease acquired by inhalation, it is scarcely likely that this is a frequent occurrence, since it has been shown by Germano that in completely dried air-currents the bacillus soon dies. Liebermeister prefers to explain the relation of typhoid to the hot and dry season by the fact that at this season the quantity of solid matter in springs is relatively larger; that the poison, in other words, is more concentrated, and therefore more virulent. Special epidemics may occur at any season. Thus the epidemic of typhoid fever at

Plymouth, Penna., alluded to, began April 10 and raged with greatest fury during May and June. Other epidemics illustrate the same truth.

Morbid Anatomy.—The characteristic morbid anatomy of typhoid fever includes the changes in the *lymphatic structures* so constantly associated with the disease. These are more striking in the *solitary glands* of the ileum and their agminations known as *Peyer's patches*. The glands are enlarged by the accumulation of outwandering and proliferated leukocytes that develop to the stage of epithelioid cells, when they become necrotic and disintegrate. The acme of this process prior to disintegration is known as *medullary infiltration*, and is reached from the eighth to the tenth day of the disease. In a recent autopsy made after death on the eleventh day typical medullary infiltration was found. The disintegration is either molecular or massive. The former is followed by a corresponding absorption; the latter, by a massive discharge of the dead cells into the bowel, resulting in the well-known *typhoid ulcer*. This, when it represents a single follicle, is small and circular, not more than from three to six millimeters (1-8 to 1-4 inch) in diameter; large and elliptical when an entire *Peyer's patch* is involved. Such a patch is usually opposite the mesenteric attachment, has its longest diameter parallel with the length of the bowel and its shorter transverse, thus reversing the relations of the tubercular ulcer. Much larger ulcers are sometimes formed by the union of others, especially toward the lower end of the bowel. The borders are commonly raised. The floor of the ulcer is usually the submucosa, or the muscular coat of the bowel, but it may be the peritoneum, and even this is sometimes sphacelated, appearing as an opaque white membrane that sooner or later breaks and the bowel is perforated. The discharge of its contents into the peritoneal cavity is followed by peritonitis, usually fatal. More commonly, the ulcer heals, and the patient recovers, but the normal glandular structure of the gut at the seat of the ulcer is not restored. Necropsy discovers ulcers in different stages of healing, sometimes all healed except the single fatal spot that has become the seat of perforation. The large intestine is also invaded in probably one-third of the cases, and the process may terminate here also in perforation. Ulceration may extend to the appendix, where, too, perforation sometimes takes place.

Similar infiltration of the lymph nodules and lymph cords of the *mesenteric glands* and of the *spleen* may occur, contributing to the enlargement of these organs. In the spleen it is associated with an active hyperemia that contributes to further enlargement, generally recognizable during life. The organ may reach twice or three times its normal size—*i. e.*, 435 to 650 gm. (14 to 20 ounces). There has even been rupture of this organ. Hemorrhagic infarcts have been found in the spleen in from four to seven per cent. of cases coming to autopsy. Abscess of the spleen has been found.

Perforation has been noted at necropsy in 5.7 per cent. of cases—that is, 114 out of 2000 autopsies in Munich; by Osler, in 2.48 per cent. of 685 cases. Schultz found peritonitis from intestinal perforation in 1.2 per cent. of 3680 cases in Hamburg in 1886-87; Liebermeister found perforation in 1.3 per cent. of over 2000 cases at Basle between 1865-72; Holscher, in 6 per cent. of 2000 cases; and Murchison, 11.38 per cent. of 1721 cases. In 4680 cases collected by R. H. Fitz the deaths from perforation were 6.58 per cent., which may be said to represent about the proportion actually occurring, since up to the date of his report nearly all died. It occurred in only one of 105 soldiers treated at the University Hospital in the fall

of 1898. The range of percentage of perforation may, therefore, be put down at from 1.2 to 11.38 per cent.

As to the location of perforation, Hawkins found it in 61 of 72 cases in the ileum, 3 in the cecum, 3 in the appendix, and 5 in the colon, most of the latter being in the sigmoid flexure. In 167 cases collected by Fitz the ileum was perforated in 136, the large intestine in 20, the appendix in 5, Meckel's diverticulum in 4, the jejunum in 2. The number of perforations is usually 1, but Fitz reports out of 167 cases, 2 in 19, 5 in 3, 4 in 1, several (*sic*) in 4, and 25 to 30 in 2. The accident is most frequent in the third week, or close to the third week. It is more frequent in men.

The *liver*, among organs more rarely affected, shows cloudy swelling, granular and fatty degeneration of its cells, lymphatic nodular areas, and even liver abscess with pylephlebitis, and acute yellow atrophy. Abscess of the liver was found 12 times in the Munich necropsies, and acute yellow atrophy 3 times. Pylephlebitis has followed abscess of the mesentery and perforation of the appendix. Typhoid bacilli are often found in the gall-bladder in fatal cases; in Chiari's reports* 19 out of 22; in Simon Flexner's, 7 out of 14. Perforation of the gall-bladder is sometimes met, and Keen has collected 30 cases in his book on the "Surgical Complications and Sequels of Typhoid Fever," 1898. Nine cases of *abscess of the spleen* were collected by Keen, who also reports a leukemic spleen that seems to have been caused by typhoid fever.

In the *kidneys* there may be cloudy swelling and granular degeneration of renal cells; more rarely acute nephritis, which may even be hemorrhagic; also miliary abscesses in which typhoid bacilli have been found. Diphtheritic and catarrhal inflammation of the pelvis of the kidney and catarrhal inflammation of the bladder are occasionally present.

Changes in the *respiratory organs* are often found. Among the rarer of these are edema of the glottis, ulceration of the larynx, and even necrosis of the laryngeal cartilages. Hypostatic congestion of the lungs is quite common; pneumonia is more infrequent. Even gangrene of the lungs was found in 40 of the Munich cases; abscess, in 14; and hemorrhagic infarction, in 129. Pleurisy and empyema are rare events. Dr. Arthur V. Meigs† has described changes of a hemorrhagic character in the lungs, and others in the muscular and nervous systems, the essential relation of which to typhoid fever remains to be demonstrated.

In the *circulatory system* there may be thrombosis of veins, especially of the femoral, causing the not very rare symptom of milk leg; more rarely there is thrombosis of the femoral artery, which may be preceded by embolism. Endocarditis and myocarditis may be present. The latter condition is attested by a yellow, soft, and flabby muscle seen after death.

As to the *nervous system*, notwithstanding the intensity of the nervous symptoms at times, meningitis is a rare event, though both serious and purulent forms have been met, typhoid bacilli being found *in loco* as the apparent cause; also thrombosis of cortical veins and parenchymatous changes in nerve-trunks, even when there have been no symptoms of neuritis. Abscess of the brain has also been found with the bacillus typhosus *in loco*. In the *muscular system* granular and hyaline transformation of voluntary muscle may occur, as in other fever processes.

Abscesses in the parotid gland are a familiar complication; more rarely, abscesses in the intermuscular tissue. General invasion of all organs and

* "Prager medicinische Wochenschrift," 1893, No. 22.

† "Proceedings of the Pathological Society of Philadelphia," 1890.

of the blood by the typhoid bacillus was found once in William Osler's wards at the Johns Hopkins Hospital by Simon Flexner.

Typhoid Fever without Enteric Lesions.—A few years ago typhoid fever without enteric lesions would have been considered an impossibility. This can no longer be claimed. Cases have been reported by Sidney Philips, J. W. Moore, Simon Flexner, and others, without these lesions. In doubtful cases the Widal reaction and the presence of bacilli as determined by cultures must be appealed to, such examinations being suggested by other symptoms.

Symptoms and Course.—A certain *period of incubation* is necessary after the successful implantation of the bacillus before typhoid fever arises. This varies from a week to two weeks and even longer. The period of incubation is usually without symptoms, but a sense of weariness and indisposition to exertion, the latter often overcome by force of will, may be present; so may a want of appetite and a slight coating of the tongue. These symptoms, more strictly speaking, belong to the prodrome, and are in turn not sharply separated from those of the disease itself, which usually sets in very gradually, and is often quite advanced before suspected,—indeed, sometimes well advanced, constituting the “walking” or “ambulatory” typhoid. In *children the onset is less gradual*. There may be headache, anorexia, a furred tongue, nausea, chilliness, but only rarely a decided rigor. The disease may be ushered in by *pain* in the back or legs or muscles and *nosebleed*. The latter has always been considered characteristic, and yet I meet it less frequently than might be expected from the text-book statements. More common is *looseness of the bowels*. All this time there is slight fever, and the patient feels wretched. The fever and the discomfort increase, and finally he goes to bed. The tendency to looseness of the bowels and epistaxis, more than any other symptoms of this group, justify strong suspicion of the existence of typhoid fever. Yet one or both are quite often absent. Certain epidemics are more apt to be attended by diarrhea than others. The *abdomen* soon becomes slightly distended and tympanitic, and pressure in the right iliac fossa will usually elicit *tenderness with gurgling*. At times there is *colicky pain* of varying severity independent of pressure; at others the *gastric* symptoms are marked and there are nausea and *vomiting*.

Usually about the eighth day, rarely later and sometimes a little earlier, *rose-colored spots* make their appearance on the skin of the abdomen and chest, more rarely elsewhere on the body. These call for further description. They are usually bright red in color, and are well compared to a fleabite. They are very slightly, if at all, raised above the surface and disappear on pressure, to return instantly after its removal. Their number varies greatly. Sometimes they are very numerous, oftener there are four or five to ten, again one or two, most rarely none. When numerous, they occur in successive crops, each crop lasting from two to four days. Histologically, they are circumscribed, actively hyperemic areas, the hyperemia being excited by some irritant, which may be the typhoid bacillus itself, since it has been found in the spots. Only in the most malignant cases is there any blood found outside of the vessels, and when this occurs, the spots can be made to disappear but partially on pressure. The association of roseolar spots is so intimate with the disease that they have been regarded as pathognomonic. Rose-colored spots are much more uncommon in children.

In addition to rose-colored spots, *sudamina* are often present in large

numbers on the skin, especially when the disease is associated with much sweating, but their occurrence is by no means constant, and their association with other diseases in which there is perspiration is well known. More rarely, *petechia* and *vibices* are noted in adynamic forms of the disease. An *erythema* is quite often found on the skin of the chest and abdomen. Peliomatous patches—the *tâche bleuâtre*—sometimes are found on the skin of the thorax, abdomen, and thighs; also the *tâche cérébrale*—a red line, produced on drawing the finger-nail over the skin,—but neither have any symptomatic significance. *Herpes* is so rare that it is often spoken of as *negatively pathognomonic*. *Jaundice* is occasionally seen, and may be the result of an obstructive cholangitis excited by the bacillus.

Enlargement of the spleen is an almost constant clinical feature of typhoid fever. If the vertical dullness exceeds the depth of two ribs and an interspace, enlargement is present. Not only may such enlargement be recognized by percussion, but by palpation as well. Clinicians generally lay great stress on palpation, and enlargement may sometimes be detected by it when the organ eludes percussion by reason of tympany. Hermann Eichhorst advises the following method of examination: Put the patient in the right diagonal position, and lay the finger gently between the anterior ends of the eleventh and twelfth ribs, when the enlarged organ can almost always be felt with every deep inspiration of the patient, in spite of meteorism. At times the outline is indistinct, at others both the tip and anterior edge of the organ can be distinctly located. Strong pressure should not be exerted by the fingers, for in this way the spleen may be insensibly pressed backward into the excavation of the left hypochondrium. Enlargement can generally be detected at the end of the first week or in the first half of the second week, when the organ may reach twice or three times its normal size. By the end of the third week it begins to diminish in size. The enlargement may be accompanied by tenderness. Enlargement of the spleen is less frequent in cases occurring late in life.

Early, too, in the disease the patient may have a slight *cough*, unassociated with physical signs, or at most those of a mild bronchial catarrh.

The *fever* is at once the most important and characteristic symptom, and from the temperature alone a diagnosis can be made. During the *increment* of the disease it exhibits a peculiar, tide-like evening rise and morning fall, while the temperature of each morning and evening is from one and a half to three degrés higher than that of the previous morning and evening. The patient is rarely seen at the very beginning of this first stage, but should he be, it will be found to last commonly a week. Frequently it is succeeded at the end of four or five days by the acme or *fastigium*, in which are continued the evening rise and the morning fall, but the evening and morning difference is less marked, the tidal character is no longer present, and the temperature is high throughout. The average duration of the fastigium is five to eight, rarely ten days, being longer in severe cases and shorter in milder ones. It is during it that we meet the maximum temperature, quite often 105° F. (40.5° C.) or a little above, more rarely 106° F. (41.1° C.). A temperature of 106° F. is not infrequently followed by recovery, but while 107° F. (41.6° C.) and 108° F. (42.2° C.) and even 109° F. (42.7° C.) are met, such cases have invariably, in my experience, terminated fatally.

The fastigium is succeeded by the third stage, or *period of decrement* or decline, in which the reverse of the initial stage is shown by an evening

temperature lower than that of the previous evening, and the morning temperature lower than that of the previous morning, but with the evening temperature still higher than that of the morning of the same day. This decline continues until the normal is reached, and from one to two weeks are consumed before that is attained. The whole is much better shown and more easily understood from a chart than from a description in words. Such a chart of the temperature uninfluenced by treatment is seen in figure 1, although the rise and fall are not always as regular as indicated. In a typical case one might safely place the first stage at four days to a week; the second, or fastigium, at seven to ten; and the third, about as long as the second, the shorter period corresponding to a mild case and the longer to a severe one. The fever does not always reach the higher temperature shown

Fig. 1.—Temperature Chart of a Typical Case of Typhoid Fever Uninfluenced by Treatment.

in the chart, and sometimes the maximum never reaches 102° F. (38.9° C.). On the other hand, there is sometimes a difference of three or four degrees in the morning and evening temperature, and the latter may drop to the normal. In ordinary cases the evening temperature falls to the normal in the course of the fourth week, but in severe cases the temperature keeps up during the fifth and even sixth week, these cases having almost invariably extensive ulceration with great tenderness of the abdomen and meteorism. Many of them terminate unfavorably by hemorrhage or perforation.

When the disease begins with a *chill*,—a rare event,—the temperature rises more rapidly in the beginning. Sudden falls of a decided character

may occur in consequence of hemorrhage from the bowels or the nose or from collapse after perforation of the bowels. Sudden rises are produced by indiscretion in diet and overexertion or the supervention of some acute inflammatory affection, as pneumonia, or ptomain absorption.

Copious *sweating* characterizes some cases of typhoid fever, though the skin is more commonly dry. Sometimes, during the reaction after a cold bath, there is perspiration. The profuse sweats first alluded to are not attended by a reduction of temperature. On the other hand, they are sometimes present when the temperature is highest. Cases of recurring paroxysms of chill, fever, and sweat are reported, which simulate intermittent fever, and may reasonably be mistaken for it.

The *pulse* is only moderately frequent, 90 to 120 being the usual range, while a proximity to 100 is quite frequently maintained. In grave cases it becomes more frequent, 140 or more; when, if maintained, it is a rather unfavorable symptom, due to high temperature or complications. Temperature and pulse do not always increase *pari passu*. Dicrotism may occur with frequent pulse, but dicrotism also occurs in the early stage, when it is regarded by some as diagnostic. During convalescence the pulse gradually resumes its normal character, and sometimes becomes abnormally slow, falling to 30 or less. I have recently had a case in which the pulse fell as low as 18, and continued for one day between 20 and 36.

The *breathing rate* commonly advances with the rate of the pulse, but is sometimes increased in frequency by temporary causes and rarely is disproportionately slow. In a very striking case of my own at the University Hospital the rate fell to twelve in a minute, and continued thus for an hour.

The *heart-sounds*, at first natural, grow less loud as adynamia progresses, and the first sound may even disappear in grave cases. Sometimes a soft systolic murmur develops at the apex, usually at the end of the second week. Sometimes it acquires greater intensity. It has been especially studied by M. G. Hayem,* who ascribes it not to an endocarditis, but to a relaxation of the muscle which results in imperfect apposition of the valves and a consequent regurgitation. This murmur disappears as recovery takes place, and the heart-muscle grows strong.

As the disease advances, the *tongue*, previously furred, tends to become dry and brown, clearing, however, at the edges and tip as the case improves. In severe cases, especially if the mouth is not kept clean, *stomatitis* with fissures and bleeding may occur, and sordes may collect on the teeth, while the lips become covered with black crusts, constituting the "fuliginous coating." These phenomena are almost unknown with the bath treatment. Mild grades of *pharyngitis*, producing difficulty in swallowing, sometimes usher in the attack, more particularly in certain epidemics.

The *diarrhea* of typhoid fever has been alluded to. Usually corresponding in severity with the extent of the local lesion, it is seldom troublesome or difficult to control, and is sometimes absent throughout. The stools may be grayish yellow, and about the consistence of pea soup.

Meteorism in moderate degree is an almost constant symptom. The distention by gas is commonly ascribed to atony of the bowels. Its presence in high degrees adds to the seriousness of the case, since it corresponds usually with the extent of bowel lesion, and soon succeeds perforation.

Hemorrhage from the bowels, also a consequence of intestinal ulceration

* M. G. Hayem, "Des manifestations cardiaques de la fièvre typhoid," "Le Progrès Médical," 17 Juillet, 1875, p. 401 et seq.

and the separation of sloughs, is a serious symptom, but by no means always fatal, though large quantities of blood are sometimes discharged *per anum*, The occurrence of such hemorrhage is followed by a rapid reduction of the temperature, as shown in the appended chart, and a pallor and faintness such

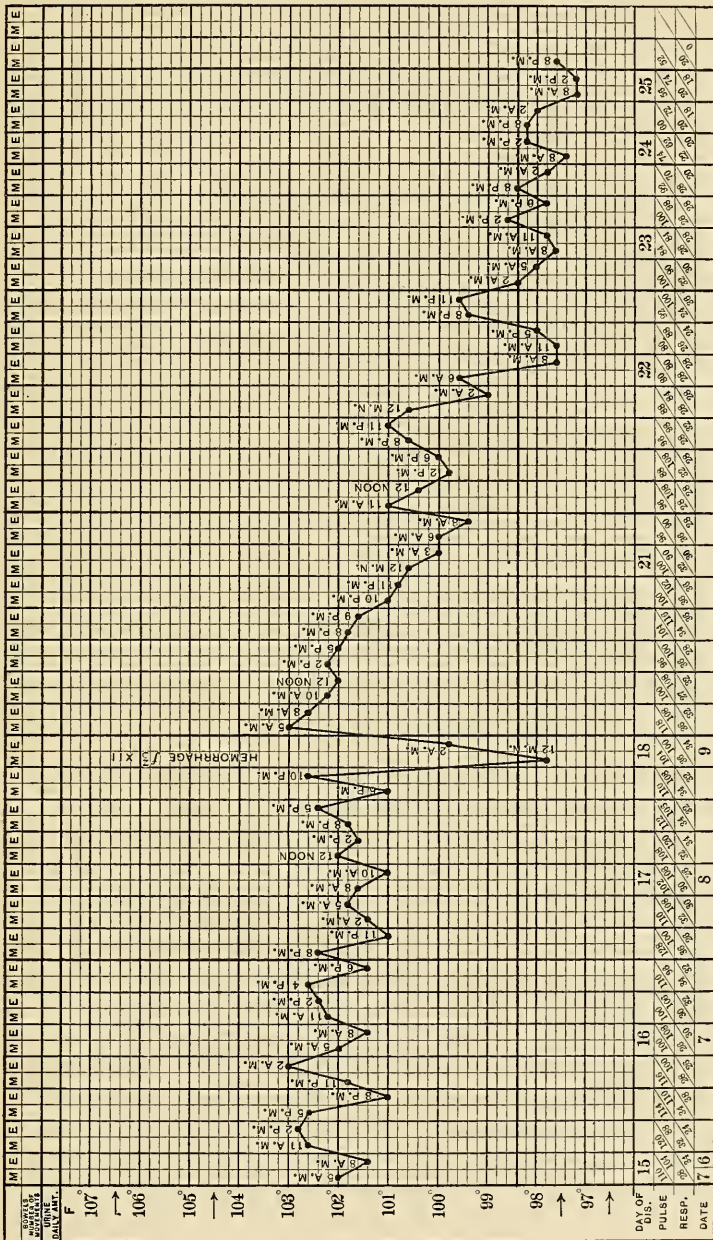

Fig. 2.—Showing Drop in Temperature Incident to Intestinal Hemorrhage.

as are common to large hemorrhages elsewhere. As stated, very profuse hemorrhages may be followed by recovery, and it is barely possible that a favorable influence may sometimes be exerted by them. Very rarely a patient will bleed to death. Hemorrhage was a cause in 11 out of 56 deaths in

Osler's 685 cases. It occurred 99 times in 2000 cases in Munich, and 8 times in 105 soldiers under my care after the Spanish-American war.

Perforation is attended by sudden acute pain in the abdomen, and symptoms of collapse. The pain is rarely circumscribed, but radiates through the abdomen; and I well remember a case when it was so high up that it seemed in the thorax and I mistook it, for a time, for that of pleurisy. It occurs most frequently in my experience in the third or fourth week, but it has happened as early as the eighth day and as late as the sixth week. In Fitz's cases it occurred in the third or fourth week in 46.5 per cent.; in four cases in the first week and one in the sixteenth week. (See also Morbid Anatomy.)

Delirium is less constantly present in typhoid fever than in typhus, and may be absent throughout. It may, however, be very active, requiring the patient to be carefully watched to prevent him from leaving his bed and seriously endangering his life. More than one victim has leaped from a window with fatal results under such circumstances. In certain cases, especially when the initial headache is very intense, this symptom continues, and to it are added fever and delirium so extreme that meningitis is simulated, though the true form of this disease rarely occurs. Such cases illustrate the "nervous form" of the disease. A tendency to drowsiness, and even to stupor, suggested the common name "typhoid," but it is less characteristic than in typhus.

Muscular tremor is a symptom in severe cases, when it would seem to indicate a muscular weakness or exhaustion, which may be an effect of high temperature or of the specific poison of the disease. Carphologia, or "picking at the bedclothes," is a symptom of which the unfavorable import has been somewhat exaggerated, probably because of the popular familiarity with Dame Quickly's interpretation in Falstaff's illness. Concurrently with these "typhoid" symptoms, the tongue reaches its maximum dryness, and may be dark and leathery in appearance, while sordes may collect on the teeth.

Bed sores are among the dangers of protracted cases.

Hiccough is an infrequent, but sometimes obstinate symptom.

Apart from an initial *bronchial catarrh*, which sometimes ushers in the disease, the typhoid patient sooner or later acquires a *slight cough*, due to hypostatic congestion of the lungs, but it is easily kept within bounds by frequent changes in the position of the patient. Occasionally, the cough is quite severe, but seldom requires more active treatment than this. The initial bronchial catarrh, too, sometimes assumes severity, while more rarely the symptoms and signs of *pneumonia usher in the disease*.

Changes in the Urine.—The urine is always dark-hued and concentrated, with a correspondingly high specific gravity. Often when the fever is high the urine contains a small amount of albumin. When complicated with *nephritis*, there is more albumin, and tube-casts are present. Recent French statistics place albuminuria, regardless of its cause, at over twenty per cent. While such albuminurias are found in grave cases, they do not appear to add greatly to the seriousness of the case, and recovery is by far the more usual termination. More rarely, nephritis in a mild form may develop during convalescence. Most rarely, it may be the initial symptom of the disease, constituting a nephrotyphoid analogous to the pneumotyphoid, when it may even mask the true disease by the severity of its symptoms. It is well named by the French—*fièvre typhoïde à forme rénale*. Only the Widal test, the intes-

tinal symptoms, and the spots clear up the diagnosis. Such nephritis may rarely be hemorrhagic. The toxic properties of urine are said to be increased during typhoid fever, especially while the cold baths are being used.

The urine may contain bacilli of typhoid fever, generally associated with albumin. The following summary from Norman B. Gwyn's paper in the "Johns Hopkins Bulletin," June, 1899, condenses our present knowledge.

"1. In quite a high percentage, perhaps from twenty to thirty per cent., of all cases of typhoid fever typhoid bacilli may be present in the urine.

"2. When present, they are usually in pure culture, often so numerous as to make the freshly voided urine turbid, and may then be detected by a cover-slip examination.

"3. Appearing generally in the second and third week of illness, the organisms may persist for months or years, probably multiplying in the bladder, the urine being apparently a suitable medium for their growth.

"4. Though often showing evidences of cystitis and marked renal involvement, the urine containing bacilli has usually only the characteristics of an ordinary febrile urine; the presence of bacilli has no prognostic importance, and their disappearance or persistence, without having induced local change, is the rule.

"5. Lastly, as shown by Richardson, irrigation of the bladder with bichlorid of mercury and the internal administration of urotropin—a compound of ammonia and formaldehyde—seem to be safe methods of removing the bacilli; thirty to sixty grains of the latter quickly removing all bacilli in six cases."

The so-called *dialo reaction* of urine, to which attention was first called by Ehrlich in 1882, is so constant in this disease as to be deservedly regarded as a symptom. It was found by John Hewetson in 136 out of 196 cases, and by Arthur R. Edwards in 128 out of 130 cases, and by Simon in 22 out of 26 cases. I have never found it absent when the test was made sufficiently early.

Three solutions are kept in separate bottles:

1. A five per cent. solution of hydrochloric acid saturated with sulphanic acid. This solution should be fresh.

2. A half of one per cent. solution of sodium nitrite.

3. Ammonium hydrate.

When it is desired to make the test, 40 c.c. of (1) and c.c. of (2) are mixed. The hydrochloric acid, acting on the sodium nitrite, liberates nitrous acid, which in its nascent state combines with the sulphanic acid, producing dialo-benzine-sulphonic acid. Equal parts of this mixed solution and urine are thoroughly shaken; enough of the ammonia is then allowed to flow carefully down the side of the tube to form a colorless zone above the urine mixture. At the junction of the two fluids a dark-garnet or cherry-red ring will form if the reaction takes place, and if the tube is well shaken, a uniform red color is imparted to the entire fluid, which, when allowed to stand for some hours, shows a characteristic olive-green precipitate, the upper layer of which, as a rule, has a still darker-green color. The *reaction occurs about the time of the appearance of the rash* and usually *continues until the twenty-second day*, but it may disappear before the end of the second week. It is, as stated, symptomatic and not diagnostic, certainly not pathognomonic, as it occurs in many diseases with high fever, among which measles and miliary tuberculosis are conspicuous. It may, however, be

regarded as negatively pathognomonic—that is, its absence is strongly presumptive against the presence of typhoid fever.

Changes in the Blood.—The state of the blood in typhoid fever early claimed attention, and even the earliest observers, beginning with Le Canu in 1837, noted a diminution of *red blood-corpuscles*. This observation has been

Black—Red Corpuscles. Red—Hemoglobin. Blue—Colorless Corpuscles.
 Fig. 3.—Chart Showing Anemia of Typhoid Fever.—(From Thayer's "Monograph.")

essentially confirmed by the most recent studies with modern accurate methods, among which those by Ouskow,* by Khetagurow, † and by W. S. Thayer ‡ are conspicuous.

At the beginning of the fever the number of red blood-corpuscles is normal and even at the upper limit of normal, because the patients are apt to be young and strong, while in some instances the initial diarrhea or pronounced sweating may cause slight concentration of the blood. During the first two weeks the number of red corpuscles gradually falls, though but slightly. With defervescence they fall off more rapidly, reaching a minimum usually about the first week of convalescence, after which there is a gradual rise to the normal, followed again by a possible slight fall when the patient gets up.

* "The Blood as a Tissue." St. Petersburg, 1890.
 † "Pathological Changes in the Blood in Typhoid Fever," Inaug. diss., St. Petersburg, 1891.
 ‡ "Two Cases of Post-typhoid Anemia, with Remarks on the Value of Examination of the Blood," vol. iv., "Johns Hopkins Hospital Reports," 1895.

The fall in the number of red corpuscles, while relatively slight, bears usually a direct relation to the severity of the case.

The *hemoglobin* is always reduced and the reduction is relatively greater than the corpuscular loss, with an even slower return to the normal. Extreme anemia, with a blood count as low as 1,300,000 corpuscles in a cubic millimeter and hemoglobin as low as twenty per cent., has been met.

The number of *leukocytes* in a cubic millimeter, normal at the beginning, tends also to *diminish* slightly throughout the disease, reaching a minimum toward the end of defervescence, increasing again with the beginning of convalescence, and reaching the normal after several weeks. More definitely the change consists in a diminution in the percentage of multinuclear or overripe elements, with a relative increase in the large mononuclear or ripe elements. Thayer regards the *absence of leukocytosis of real diagnostic value*, being in marked contrast with the distinct increase in the number of colorless corpuscles and overripe elements (multinuclear cells) characteristic of most other infectious processes. Typhus fever is unattended by blood changes, and while in a few cases of malignant pneumococcus infection there may be no leukocytosis, there is no *diminution* in the leukocytes, as in typhoid. The condition of the blood in malarial fever is practically the same as in typhoid fever, but the presence of the malarial parasite in the former is distinctive. In pure miliary tuberculosis unassociated with local inflammatory processes there is also an absence of leukocytosis. It is important to remember that cold baths have the effect of producing a decided temporary increase in the proportion of leukocytes, probably rather, as Thayer thinks, in consequence of an accumulation of white cells in the vessels of the surface than as the result of a true leukocytosis. More rarely, the leukocytes are increased. Cabot refers to four cases in which they reached 11,000, and in one 17,000, with no lesions other than those common to typhoid. Very interesting is the effect of suppuration on this reduction in the number of leukocytes. It is replaced by an increase as shown by counts after perforation, phlebitis, and otitis. Especial value is claimed for leukocytosis as a warning of impending perforation and peritonitis.

Unusual Modes of Onset. Unusual Symptoms. Atypical Forms.—

It has been mentioned that while slight chilliness is often an initial symptom, *severe rigor* at the same stage rarely occurs. It does, however, happen, as in 13 out of 79 of Osler's cases. More frequently, chills have been observed in the course of the disease from some one of the following causes:

1. At the onset of a relapse.
2. As a result of treatment, especially by antipyretics internally, guaiacol externally, or of a hypodermic injection of a sterilized culture of typhoid bacilli.
3. At the onset of complications, such as pneumonia or pleurisy or thrombosis.
4. From sepsis during convalescence in severe and protracted cases. Under these circumstances chills may be frequent, severe, and of grave import.
5. From concurrent malaria.

In epileptics who acquire typhoid fever the latter disease is very apt to be ushered in by an unusual number of epileptic *convulsions*, which continue frequent until the fever becomes established, then diminish, and finally cease, often not recurring until some time after recovery, causing the victim and his friends to believe that the chronic malady has disappeared. It returns,

however, sooner or later. The same is true of choreic attacks. Rarely, the disease is ushered in with convulsions in children. In diabetes the sugar may disappear during the fever.

Among the more unusual modes of onset should be mentioned cases beginning with severe bronchitis; those with the initial symptoms of pneumonia, including chill; those with initial symptoms of nephritis or with intense nervous symptoms, suggesting cerebrospinal meningitis. Among the latter are intense headache and photophobia, combinations rapidly passing over into active delirium, with muscular twitching and retraction of the head, constituting the *nervous* or *meningeal* form. In accordance with recent views these varieties may be considered as representing forms in which the organs especially involved are the primary and chief seats of attack by the bacillus as contrasted with the more usual intestinal form. In certain long and severe cases septic infection occurs, manifested by fever, sweats, and local abscesses in various parts of the body, including the perirectal and perinephric regions.

Among *irregular* forms is the so-called *abortive form*. This doubtful form is said to be more sudden in its onset, beginning with shivering and fever of 103° F. (39.4° C.) or higher. The rose-colored spots appear at from the second to the fifth day. The fever falls at the end of the first week or beginning of the second, commonly by crisis with a sweat, after which follows convalescence. The *hemorrhagic* is a grave variety characterized especially by cutaneous and mucous hemorrhages, and is fortunately rare. The *mild form* is sometimes so mild as scarcely to be recognized as typhoid fever and is often called gastric fever or simple febricula. There is, however, no more important lesson for the inexperienced practitioner to learn than that some cases beginning as a mere febricula may pass over into forms of great severity, and may even terminate fatally. A very rare form is the *tonsillar typhoid*, in which whitish elevations appear on the tonsils, subsequently becoming ulcers.

Complications and Sequelæ.—The recent Spanish-American war has confirmed the possibility of the coexistence of typhoid fever and of *malarial* fever, since a number of cases from among the soldiers have been reported in which not only all the necessary clinical features of typhoid fever were present, but also the Widal reaction, in which, too, the malarial organism was found in the blood. Such coexistence occurred in two of the cases under my own care in the Hospital of the University of Pennsylvania. It is, however, an infrequent event. On the other hand, a mongrel disease that is the product of the two causes, as was once supposed to be the case, and known as *typhomalarial fever*, does not exist. The term should be dropped, as it is confusing and gives rise to erroneous impressions.

Persons with tuberculosis, diabetes, epilepsy, and other forms of chronic nervous disease are as liable to typhoid fever as others, while scarlet fever, diphtheria, measles, chicken-pox, rheumatism, and especially erysipelas, may befall a typhoid case. Typhoid fever in diabetic cases is especially apt to be attended with low temperature. Typhoid fever itself predisposes to tuberculosis, and not a few patients recover from the former disease only to be attacked by the latter.

Thrombosis of the femoral vein, more frequently the left, resulting in *phlegmasia alba dolens*, or milk leg, is a complication that often greatly delays convalescence. It occurs, according to Murchison, in one per cent. of all cases. It sometimes invades both legs in succession, and may extend

into the iliac veins and vena cava, thence even into the right auricle, causing death from syncope. Unless the latter event occurs, however tedious the recovery, it takes place ultimately almost without exception. Very rarely there may be suppuration. Bacilli have been found in the thrombus. More or less phlebitis is always present. The question as to the primary event, whether thrombosis or phlebitis, is seemingly settled by this finding of bacilli, in favor of the former. *Arterial* as well as *venous thrombosis* may occur, and the former may start with embolism; femoral arterial obstruction is most common, resulting in gangrene of the leg and foot. *Embotic abscess* may occur in the kidney and lung.

Parotitis, commonly going on to suppuration, is an occasional symptom. It is the result of infection by Steno's duct.

Noma, or gangrenous stomatitis, has appeared as a complication or sequel in children. W. W. Keen records nine cases of which five proved fatal. Gangrene in other situations occurs more rarely, as in the vulva in females and in the perineum and about the anus in both sexes. This may be due to arterial thrombosis. Perineal fistulæ may follow in these cases.

It has been mentioned that *pneumonia* may usher in the disease, and a few words may be said here of the relation of the two conditions, pneumonia and typhoid fever. The term *typhoid pneumonia* is one in common use by many who have no definite notion of its meaning, and, like the term typhomalarial, has occasioned confusion. In the first place, the case may begin as a lobar pneumonia, the intestinal symptoms appearing at the end of the first week or later, at which time also the spots may appear, establishing the diagnosis, while the usual crisis of pneumonia fails to make its appearance. Again, a pneumonia may supervene in the second or third week of a typhoid fever as a complication in which the true relation is less difficult to determine. Finally, there may be a true pneumonia, to which stupor, a dry tongue, and general adynamia may be added, without the distinctive lesions of typhoid fever. This is true typhoid pneumonia, which it may not always be easy to separate from the typhoid fever beginning with pneumonia. Both of the forms of pneumonia may be caused by the typhoid bacillus or the pneumococcus. Hypostatic congestion has been referred to. Many cases formerly thus named are really instances of catarrhal or lobular pneumonia belonging to the class of inhalation pneumonias. Such may terminate in abscess and gangrene. When *pleurisy* occurs, it has the same relations to the disease as pneumonia. It is, however, more rare, but may also be purulent. An *initial nephritis* has been mentioned on page 32.

Certain *suppurative processes* sometimes included as symptoms should be regarded rather as complications than symptoms. Of these those about the *ear* are the most serious. They are, however, less frequent in typhoid than in typhus fever. They are most common in the parotid gland, where, however, the inflammatory process does not always terminate in suppuration, occasionally resolving itself with or without local treatment. The duct of Steno is probably the route of infection in these cases by the pus organisms that find conditions favorable to their work. The middle ear may be invaded, producing *otitis media*. Here the Eustachian tube becomes the route of infection. Sometimes abscesses are multiple. Not infrequently convalescence is delayed by numerous *boils*, the effect of which in keeping up the temperature must be remembered.

The *bladder* may be a seat of suppuration, and *pyuria* is not infrequently present. George Blumer found it in 10 out of 60 cases, or nearly 17 per

cent., of a series admitted to the Johns Hopkins Hospital. I have met it only once in a pronounced form in a series of 41 cases, but also in isolated cases more frequently since my attention has been called to its possibility. It is probably caused by the typhoid bacillus. The inflammation may extend to the pelvis of the kidney or start therefrom. *Orchitis* and *epididymitis* are also occasional symptoms during convalescence. Thompson S. Westcott collected 32 cases for Keen's book, "Surgical Complications and Sequels of Typhoid Fever," 1898.

Cardiac complications, including pericarditis, endocarditis, and myocarditis, are sometimes present. The latter may be a cause of sudden death.

Neuritis is an occasional complication or sequel in both the local and multiple forms. Osler found it, however, in but 4 of 389 cases. The pain may be severe and associated with the usual tenderness of the nerve trunks. I recall one patient who made a splendid recovery under the tub-bath treatment, but had the exquisitely tender toes first described by Handford. The tenderness is often so great that the bedclothing must be kept raised by a cradle. I find neuritis, too, more frequent since I have been watching for it. Even cases of optic neuritis with atrophy of the optic nerve have been reported, but it is probable that these are sequelæ of meningitis mistaken for typhoid fever. *Tetany* sometimes succeeds typhoid fever.

Two sequelæ of typhoid fever, neither of frequent occurrence, are conspicuous by their symptoms. They are *insanity* and *tubercular phthisis*. The former is often typical acute mania, requiring the utmost vigilance to prevent the patient from injuring himself and others, or from escaping from the house or jumping from a window. Although this form of insanity is often prolonged for many weeks, the prognosis is singularly favorable, and recovery, sooner or later, takes place. Tubercular phthisis, when it occurs, has its predisposing cause in the lower tone of cell life, favoring the successful implantation of the specific bacillus, and is followed by its usual consequences.

Post-typhoid *bone lesions* are surprisingly common. Sir James Paget, Murchison, W. W. Keen, Haywood, Harold C. Parsons, and others have collected many cases. They include osteitis, necrosis, and periostitis. The tibia is the favorite seat,—91 times out of 216 of Keen's collection,—next the ribs 40 times, the femur 22 times, the ulna 15, and the humerus 11. Ebermaier, in 1887, obtained from two cases of suppurative post-typhoid periostitis the bacillus of Eberth in pure culture, and since then quite a number of cases have been reported; whence pyogenic properties of this bacillus may be inferred. Other bacilli—viz., the staphylococcus, streptococcus, and pneumococcus—are, however, at times associated. Golgi also produced suppuration by injecting pure typhoid bacilli subcutaneously at a distance from the fractured ends of a long bone in a lower animal. The pus showed in culture only typhoid bacilli.

Perichondritis appears to be a frequent complication in Germany, as shown by the collections of Keen, Lüning, and Westcott—169, 13, and 14 respectively. Keen's and Lüning's lists include the same cases. The disease is certainly less common in England and America. Necrosis of the cartilages, as well as ulcers, are frequent results. All of these surgical complications are easily explained since the recognition of the bacillus.

The *typhoid spine*, to which attention was called by Gibney of New York in 1889, is a sequel of undetermined nature. There is sever pain in the back, commonly aggravated by motion. The pain may be throughout the

whole spinal region or limited to the cervical, dorsal, or lumbar portions. From the latter it may extend toward the hips. It may be a spondylitis, but is probably a pure neurosis. Allied to this condition is perhaps an obstinate periostitis of the sternum or the crest of the ilium or front of the spinal column after typhoid fever, alluded to by William Pepper in the "Text-book by American Teachers." These conditions are rare and sometimes, at least, may be coincidences.

Cholelithiasis is now a well-recognized sequel, Dufourt having reported it in 19 patients who had their first attack after typhoid fever. Further interest attaches because there is every reason to believe that the bacilli in the gall-bladder are the initial cause of the process which results in stone. Bernheim first called attention to this possibility in 1889, and is sustained by Dufourt, Milian, Hanot, Maurice, H. Richardson, Mason, W. H. Welch, and W. W. Keen.

Polyuria is a rare complication. A remarkable case was reported by Dr. James C. Wilson, at a late meeting of the Section on Medicine of the College of Physicians of Philadelphia. Such excessive polyuria must be due to an irritation by bacilli of the urinary center in the medulla.

Relapses.—These occur readily, succeeding, it used to be taught, upon premature relaxation of diet. The demand of the convalescent for change in food, and especially for solid food, is often well-nigh irresistible, but should be denied until the temperature has been normal for a week. With our present views as to the etiology of typhoid fever relapses cannot be thus explained; for, while such indiscretion in diet might reasonably be expected to renew intestinal lesions, it would not be expected to revive the life of the original cause, the bacillus. Accordingly, we must look elsewhere. As long ago as 1871 Hamernjk, quoted by Murchison and Maclagan,* suggested that the relapse is really a reinfection of the large intestine from the small by the passage of sloughs over healthy lymphoid follicles. Hugh Stewart † reiterated this suggestion in 1894, but Murchison early noted that the fresh lesions are sometimes higher up in the ileum than those of the first attack. Liebermeister believed that a part of the typhoid poison remained latent somewhere in the body, awaiting some exciting cause to bring it into activity. G. Fütterer ‡ claims to have been the first to discover the typhoid bacillus in the gall-bladder in 1888; § also that he was the first to express the opinion that relapses are caused by typhoid bacilli entering the intestines with the bile. Dupré ¶ and Chiari ¶¶ were among the first to find typhoid bacilli almost constantly present in the gall-bladder of those ill with typhoid fever, and suggested the possible responsibility of these bacilli for relapses. They may be discharged into the small intestine without harmful result after immunity is secured. Prior to this period, however, the patient may suffer a relapse. Thus may be explained the occurrence of relapses after indiscretions in diet, which stimulate the action of the liver and cause more bacilli to be poured into the bowel, thus increasing the chances of infection. Chiari's experience leads to further confirmation, since in three cases of relapse the number of bacilli in the gall-bladder was very large. B. Curshmann, in his paper on typhoid fever in Nothnagel's

"Encyclopedia of Practical Medicine," says of relapses: "Undoubtedly their development is to be attributed to the re-entrance into the circulation of living typhoid bacilli which, after the primary attack, were left behind in various organs; and associated with this, more or less complete development of the local and general typhoid lesions occurs."*

It has been usual to regard as necessary to the diagnosis of relapse the presence of those symptoms essential to the primary diagnosis—viz., the characteristic spots, a return of the tidal or step-like temperature, and, scarcely less so, the enlarged spleen, and all of these after complete defervescence. In my experience this dare not be insisted upon. The attack is, however, usually less severe, the duration *shorter*, and recovery the rule. Relapses are to be distinguished from *recrudescence*, which is a simple return of fever, often induced by numerous causes, including lapses in diet, too much excitement, and the like. Relapses may be multiple. Transverse markings on the finger-nails incident to multiple relapses are sometimes noted. The number of relapses varies greatly in the experience of different observers—from one to eighteen per cent. Of 112 cases admitted to the Hospital of the University of Pennsylvania from the various military camps of the country, in the fall of 1898, there was a percentage of 10.7. Certainly it is smaller with the bath treatment.

Relapses are more frequent in young persons than in older ones.

Diagnosis.—Typhoid fever is usually easily recognized by the fairly well-trained medical man, while the experienced hospital physician may even know the disease by the dull, dusky facies. At other times diagnosis may have to be delayed until the distinctive signs appear. The peculiar range of temperature is the most distinctive symptom, and from it alone the diagnosis may be made. The rose-colored spots, occurring about the eighth day, are conclusive if present, but they are occasionally absent. Diarrhea is less constant, and in my experience nosebleed still less so, but more characteristic. Both, however, require to be weighed in association with other symptoms. No one symptom is pathognomonic.

The resemblance of typhoid fever to certain cases of *rapid consumption* has long been recognized, but the modern temperature chart has greatly diminished the difficulty of distinguishing them. Certain cases of *malarial fever*, especially the autumnal type, also very closely resemble typhoid, but here, too, the temperature diagram is not identical, while the usually easy recognition of the malarial organism completes the solution. Where the two diseases are concurrent, as is sometimes the case, the difficulties are increased.

Mention has been made of the close resemblance of the so-called nervous variety of typhoid fever to *cerebrospinal fever*, and it is sometimes so misinterpreted. As the disease progresses, however, the distinctive signs develop and the correct diagnosis is gradually made. Further, unless an epidemic of cerebrospinal meningitis prevails, the probability that this combination represents the early stage of typhoid fever is far greater than that it is cerebrospinal meningitis. The popular term, "brain fever," now passing into disuse, doubtless included many of the cases of nervous typhoid.

More misleading, even though less frequent, are the cases beginning

*The term *recrudescence* is not always similarly used. Thus Curschmann, in the article alluded to, regards *relapse* and *recrudescence* as due to the same cause and calls it *relapse* if it succeeds upon a perfectly afebrile period, and *recrudescence* if the re-attack occurs during the period of *involution* before the declining temperature has completely returned to the normal. I prefer to retain the distinction given in the text, which is also that adopted by Osler.

with decided pulmonary symptoms suggesting *pneumonia* rather than typhoid fever, and unless the physician is awake to the possibilities of such a beginning and watches further developments the case may be regarded as one of typhoid pneumonia. Doubtless some cases that are still regarded as lobar pneumonia are typhoid fever. Such a mistake might have been made in the case reported by Osler in the third edition of his "Text-book," when only the symptoms and morbid anatomy of pneumonia were found, but in which pure cultures of the typhoid bacillus were isolated from the lungs, liver, kidneys, and spleen. No lesion of the intestine and no other organisms were present.

Certain cases of *concealed suppuration* resemble typhoid fever in the symptoms produced, and may for a time mislead. But again the temperature chart, after a few days' observation, will solve the question. It is in such cases that a study of the blood is of value—the presence of leukocytosis pointing to suppuration, and its absence, to typhoid.

Of specific aids to diagnosis the isolation of the bacillus is attended with many difficulties, since the tapping of the spleen is not considered justifiable, and cultures from the blood and feces are difficult to obtain and uncertain. *The serum diagnosis, or the Widal or Widal-Grübler reaction*, which depends upon the fact that the diluted serum of a patient suffering from typhoid fever will cause actively motile typhoid bacilli to lose their motility and to become aggregated into clumps, is the best aid at hand. The active principle underlying this reaction is the presence in the blood of a substance termed *agglutinin*. In many diseases this substance is present, and it is found to be specific in its reaction to the causal bacterium. However, in some normal sera a non-specific agglutinin is found, which will produce the agglutination of several varieties of bacteria. The test may be said to be pathognomonic, but, because of conditions to be spoken of later, not always applicable as an aid to the immediate diagnosis of a doubtful case. Kneass and Stengel* report that in 2383 cases of typhoid fever the reaction was present in 95.5 per cent. of the cases, and that in 1365 non-typhoid cases it was absent in 98.4 per cent. of the cases. Taking these statistics, the absence of the reaction in 4.5 per cent. of the typhoid cases may be due first, to faulty clinical diagnosis, for at the present time there is reason to believe that there are infections caused by bacilli of the typhoid-coli group, the sera of which will only agglutinate these modified types, which have been termed paracolons and paratyphoid infections. Second, it may be due to the fact that in these cases the test was not applied continuously during the supposed attack of typhoid fever, since from statistics collected by Hermann Biggs, of the Health Department of New York City, the serum of typhoid patients gave the reaction during the first week in about 70 per cent.; during the second week in about 80 per cent.; and during the third and fourth weeks in about 90 per cent. of the cases. Thus in cases clinically typhoid the test should be made every two or three days during the disease before it can be said that the reaction is absent. This late reaction, of course, is of little practical value, since the diagnosis will have been made much earlier by the more usual methods. The reaction has appeared for the first time as late as the forty-second day, and in a few isolated cases has remained absent throughout the course of the disease. Indeed the reaction has been found as long as eight years after recovery.†

*Gould's "Year-book," 1808.

†"Clinical and Scientific Contributions upon the Value of the Widal Reaction, based upon the Study of Two Hundred and Thirty Cases," Philadelphia Med. Jour., vol. iii. p. 778.

The presence of the reaction in 1.6 per cent. of non-typhoid cases is due either to faulty technique, *i. e.*, the dilutions were not high enough since the agglutinin found in some normal sera will agglutinate the typhoid bacilli in insufficient dilution; or to the fact that the patient may have passed through a typhoid infection some months previous, because the reaction has been found in some cases to be present many months after the recovery from the disease. It may occur as early as the third day, but is usually observed about the seventh day. It gradually becomes more marked as the disease progresses, and is commonly present in the blood of convalescents, and for months after recovery, though in some cases it disappears before the end of the disease. It is also true that the severer the infection, the more marked the reaction, and vice versa. Pleural and pericardial effusions, the bile, the milk, and to some extent, the urine of typhoid fever cases, as well as the blood serum, possess this agglutinative property for typhoid bacilli.

Widal, in his original communication, described the reaction as it occurred *in vitro*, as follows: "The blood or serum to be tested was added to either a young bouillon culture, or to sterile bouillon which is at once inoculated with the bacillus. In the former case the reaction with the typhoid serum appears usually within two or three hours, and consists in the clarification of the previously turbid fluid and the formation of a clumpy sediment composed of accumulated bacilli. In the latter case the tube is placed in the incubator, and within fifteen hours the reaction is manifest in the growth of the bacilli in the form of a sediment at the bottom of the tube, the fluid remaining nearly or quite the same." This method, of course, is impracticable from a clinical point of view, nor is there any attention paid to the degree of dilution or to the time necessary for the agglutination to take place.

There are several details in the technique of this test which require attention, in order to make it of value as an aid to diagnosis. I append the method employed at the William Pepper Laboratory of Clinical Medicine, because experience has proved its accuracy. A strain of typhoid bacilli is selected which by experiment is known to be easily agglutinated by sera from undoubted cases of typhoid, and which gives little or no reaction to normal sera. The stock culture of this strain of bacilli is preserved on slanted agar at room temperature, and sub-cultures made once a month. For the test, a sub-culture eighteen to twenty-four hours old is used. From this culture an emulsion is made in physiological salt solution. This emulsion is examined in the hanging drop with a power of 800 to 1000 diameters, and should be entirely free from clumping, the bacteria should be actively motile, and the number of bacteria to the field should not be too great. If any clumping is present, the emulsion should be filtered through a sterile filter paper. The blood is collected in a sterile capillary tube having an enlargement in the middle. After it is collected the ends of the tube are sealed in the flame. One drop of the clear serum is diluted in five drops of a physiological salt solution (dilution 1 to 5). One drop of the prepared emulsion of typhoid bacilli and one drop of the diluted serum are then placed on a cover glass and examined as a hanging drop. If no agglutination takes place within ten minutes the reaction is said to be negative; but, if agglutination does take place within that time, it may or may not be positive, since normal sera may agglutinate the typhoid bacilli in the dilution 1 to 10. A dilution 1 to 50 is then made: one drop of the diluted serum (dilution 1 to 5) is added to 10 drops of

the bacterial emulsion in a watch glass. A drop of this mixture is then examined in a hanging drop; and if agglutination takes place within an hour and there is no clumping in the control, it is said to be positive; otherwise it is said to be negative. This method furnishes a means for accurate dilution, but is, of course, less practical than the dried blood method suggested by Wyatt Johnson, of Montreal, because of the necessity of having at hand a glass capillary tube.

In the dried blood method the same technique may be followed as that described above. A drop of the dried blood, which has been collected on absorbent or smooth paper, or on a piece of glass, is diluted with five drops of a physiological salt solution, making an approximate dilution of 1 to 5. The test should then be carried out in the same manner as in the serum method.*

Diagnosis of Perforation.—In view of recent increased success of operation for perforation, an early recognition of this accident becomes important, to which end a close watch should be kept for warning symptoms. Among the latter is hemorrhage from the bowels, for, while by no means always followed by perforation, it precedes this accident in a certain number of cases. Its occurrence should, at least, excite increased vigilance in looking for the signs of perforation, and particularly suggests a count of the blood with a view to discovering leukocytosis. To this end frequent counts should be made. If leukocytosis be found, there is additional evidence of impending perforation, though it is to be remembered, too, that abscess in the parotid and otitis media also produce leukocytosis. Perforation itself is usually ushered in by sharp pain, tenderness, rigid abdomen, lowered temperature, frequent pulse, followed later by meteorism, vomiting, the pinched features, and cold, clammy skin of collapse. If the perforation is in the appendix, the symptoms are those of perforation succeeding appendicitis. It may occur in the mildest cases, and in such especially, the appearance of localized pain and tenderness may also be regarded as a warning. Tympany is not always present, while it is often evident when there is no perforation.

In a second class of severe cases where there is delirium or stupor, abdominal distention may be the only symptom. In a few instances there are no evident signs and the perforation may be first found at autopsy. This occurs commonly in cases of unusual gravity, where the event is masked by the severity of the symptoms.

Prognosis.—The mortality of typhoid fever varies so much in different epidemics and under different circumstances that statistics are of doubtful value in measuring fatality. Extremes of mortality claimed are as low as one per cent., and even less by the Brand bath method as carried out on the continent of Europe, and as high as fifty-five in army practice during campaigns and among negroes. The average of all may be put down approximately at from ten to thirty per cent. before the Brand cold tub treatment was instituted. Prior to this, hospital treatment appeared less successful than that of private practice. Since its introduction, because of the greater ease with which that treatment can be applied in hospitals, this can hardly be said to be the case.

In private practice a decided majority get well, fully 80 per cent., with rest, liquid diet, and family nursing. With skilled nursing, judicious feeding, and symptomatic treatment, a larger proportion of recoveries takes place,

* See also a paper on the "Principles Underlying the Serum Diagnosis of Typhoid Fever and the Method of Its Application," by Prof. W. H. Welch, *Jour. Am. Med. Assoc.*, August 14, 1907. An interesting résumé of the development of our knowledge of the subject will also be found there.

say 90 per cent. In hospitals where the Brand method is correctly carried out there is an easy reduction of mortality to 7 per cent. and less. In this country the results have not been quite so satisfactory as on the continent of Europe. The mortality of William Osler's cases at the Johns Hopkins Hospital, Baltimore, has been 7.3 per cent. My own, at the Hospital of the University of Pennsylvania and at the Philadelphia Hospital, has been 7.3; that of James C. Wilson and others at the German Hospital, up to January 1, 1896, 7.25 per cent.—astonishingly uniform results.* Brand's own mortality has been but 1 per cent. Of my own cases treated by the Brand method all who died perished through perforation or hemorrhage of the bowels. Among the soldiers under my care at the University Hospital in 1898-99 treated by the Brand method the mortality was 4.5 per cent. Among causes which have contributed to reduce percentage of deaths is the including of mild cases as determined by more accurate diagnosis.

Unfavorable symptoms are persistent high temperature, above 105° F. (40.5°C.), low muttering delirium, extreme tympany, hemorrhage from the bowels, and the signs of perforation. Walking typhoid has been almost always fatal in my experience, exhaustion being apparently caused by the continued muscular effort during fever.

Sudden death by syncope occasionally occurs, sometimes when least expected, during convalescence, or it may happen during the acme of the fever. In either event the immediate cause is not always discoverable, evident lesions being wanting in most cases. Pulmonary thrombosis and myocarditis have been found at autopsy in these obscure cases. Sudden death is much more frequent in men than women,—114 to 26, according to Dewèvre's statistics,—a surprising and almost incredible difference.

The prognosis in children under fifteen is especially favorable. Recovery takes place in them with few exceptions, while I have been struck with the number of fatal cases in young people from eighteen to twenty-two. Then follows a period favorable to recovery, but after forty the mortality again increases. The dangers at this older age appear to be from complications, especially pneumonia, as the symptoms peculiar to the disease are not increased in severity.

The prognosis in pregnant women is grave. In the first place, the pregnant woman usually aborts in the second week. This is, however, not invariably the case, Dr. G. H. B. Terry reporting † a case of undoubted typhoid fever occurring in a woman during the fourth month of her third pregnancy. She recovered, and on April 5 following gave birth to twin girls, healthy and weighing respectively six and seven pounds. According to L. Brieger, the mortality was 20 per cent. of cases treated by other than the bath method. The results of the bath treatment seem to be better. I recently had under my care two pregnant women at the end of the fifth and sixth months respectively, now recovered, who were treated throughout by cold tub-baths without accident. Under any circumstances more women die of typhoid than men—this, too, though the disease is more frequent in men than in women. Fat persons bear the disease badly.

Hemorrhage and perforation seem to be in no degree diminished by the Brand bath treatment. On the other hand, careful investigation shows that these accidents are not more frequent, as has been alleged.

* These are the figures published in my first edition. In his third edition Osler reports the mortality up to date (1898) at the Johns Hopkins Hospital 7.3 per cent.—a trifle less than that to date of his second edition.

† "Medical News," February 16, 1901, p. 263.

Death in typhoid fever may be the result of any of the following causes: exhaustion incident to prolonged illness, hemorrhage, peritonitis, shock due to perforation, intoxication by the toxin of the disease, or complications such as pneumonia or nephritis. As already intimated, sudden death sometimes occurs inexplicably.

Treatment.—*Rest and Diet.*—The primary conditions of a successful treatment of typhoid fever are rest in bed and a liquid diet, of which milk is the type. No one questions the necessity of putting the typhoid fever patient absolutely at rest in bed and not permitting him to rise for any purpose until convalescence is thoroughly established. That the diet should be liquid is as little disputed, while milk is generally conceded to be the safest form. It should be given at stated intervals, say once in two hours, in doses of from four to six ounces (118.28 to 177.42 c. c.) or even eight ounces (236.56 c. c.), as circumstances determine. Very rich milk is not desirable, hence such milk should be diluted with water or carbonic acid water, Vichy, or lime-water. The stools should be closely watched for undigested fragments of casein, and when these are present the milk should be reduced in quantity or further diluted. If there is diarrhea, the milk should be boiled while this lasts, and in obstinate cases peptonized. Animal broths of mutton or of chicken, also beef-peptonoids, may be associated with milk when change is demanded, but they are not as convenient, while beef-tea and essences are harmful. When the stomach is very irritable, albumen water may be substituted, in the proportion of the whites of two eggs to a pint of water, to which may be added a little lemon, or whisky or brandy if stimulants are indicated. Wine whey may be associated or substituted where, for any reason, milk cannot be used. In extreme feebleness of digestion peptonized milk may be administered by the rectum, but this is rarely necessary. Not more than four ounces of any nutriment should be administered at one time by the rectum, for this organ soon becomes intolerant of large doses.

While the nourishment above described fulfills also the indications for free ingestion of liquids, with a view to favoring elimination by the kidneys and bowels, plain water may also be freely given in the intervals between nourishment.

There can be no reasonable objection to enlarging the dietary of ordinary cases of typhoid fever by any easily assimilable albuminous saccharine or amylaceous food. It is a mere matter of convenience. Typhoid fever does not differ from other cases of fever in demanding simple and easily assimilable food. It matters not much what it is, of the kinds referred to. It may be that we have been needlessly restricted in the past. Many cases are so ill that they can with difficulty be made to take any food, and whatever they will take most easily is best. On the other hand, it is evident that in the emergencies of hemorrhage and perforation a minimum amount of nourishment should be given, and I sometimes allow such patients to go many hours without food. In this disease, as in others, we must treat the patient and not the disease. The list of articles named by Shattuck* and embodied in the footnote includes foods that may be added to or substituted for milk.

The Brand Bath Treatment.—In addition to rest and liquid nourishment the treatment that my own experience and a careful study of the experience

*The following list, by Frederick C. Shattuck ("Diet in Typhoid Fever," "Jour. Am. Med. Assn.," 1897, xxix. p. 51), includes many allowable articles:

1. Milk, hot or cold, with or without salt, diluted with lime-water, soda-water, Apollinaris, or Vichy; peptonized milk; cream and water (*i. e.*, less albumin); milk with white of egg, buttermilk, kumiss, matzoon, milk whey, milk with tea, coffee, cocoa.

2. Soups: Beef, veal, chicken, tomato, potato, oyster, mutton, pea, bean, squash; carefully strained and thickened with rice (powdered), arrowroot, flour, milk or cream, egg, barley.

of others place easily at the head, in every case when it can be carried out, is the cold tub-bath treatment, commonly known as the Brand treatment. Our method in the Hospital of the University of Pennsylvania is as follows:

Before the bath the patient is first encouraged to empty the bladder, and if sweating, he is wiped dry. He is then covered loosely with a sheet and gently lifted into the bath sufficiently filled with water at 70° F. (21° C.), provision being made to rest the head upon an air-cushion or platform. Unless very weak, he may at first step from the edge of the bed into the tub, which should be lower than the bed. During the bath he is vigorously rubbed by the nurse, and encouraged also to rub himself. A compress wrung out of ice-water or an ice-cap is kept upon his head, or water at the same temperature is poured at intervals upon it, say, three times in the course of the bath, or the head is sponged with cold water from time to time. This is important in severe cases with decided nervous symptoms. At the end of fifteen minutes he is lifted on the bed, which has been previously protected with a mackintosh and blanket. The wet sheet is replaced by a dry blanket, and the patient is rubbed dry. When this is accomplished, the under blanket and mackintosh are withdrawn and he is comfortably covered.

As soon as the patient ceases to shiver after his removal from the bath, which is usually in twenty minutes, the temperature is taken with a view to determine the effect of the bath. If delayed longer he may be in a restful sleep, and to wake him for the purpose of taking his temperature is needlessly disturbing. After this the temperature is not again taken until three hours after the bath. If then it exceeds 102° F. (39° C.), the bath is repeated. If the temperature is between 101° F. (38.2° C.) and 102° F. (39° C.), it is taken again in an hour; if between 100° F. (37.8° C.) and 101° F. (38.3° C.), in two hours; if below 100° F. (37.8° C.), not until three hours, but whenever the temperature exceeds 102° F. (39° C.) the bath is given, provided three hours at least have elapsed since the previous bath. This makes more than eight baths in the twenty-four hours impossible.

The effect of the bath upon the temperature varies with the stage of the disease; the reduction during the first week being often less than one degree, while toward the end of the second week and in the third week a fall of two or more degrees is quite usual. Fig. 4 shows these effects very nicely. In addition to the lowered temperature the immediate effect of the bath is to add strength to the heart and volume to the pulse. The shivering, which begins from five to ten minutes after the immersion, is not allowed to interfere with the continuance of the bath, and it very rarely happens—indeed, scarcely ever—that anything occurs to interrupt the bath. It would be wrong, however, to say that there are no conditions under which it should be discontinued and the patient at once returned to bed. Such conditions would be an almost absolute pulselessness with a blue, cyanosed appearance of the skin. Should this occur, hot-water bags should be applied to the feet and legs after the patient is put to bed.

The more remote effect of the bath may be said, in a word, to be milden-

"3. Horlick's food, Mellin's food, malted milk, somatose.

"4. Beef-juice.

"5. Gruels: Strained corn-meal, crackers, flour, barley-water, toast-water, albumin-water with lemon-juice.

"6. Ice-cream.

"7. Eggs, soft boiled or raw, egg-nogg.

"8. Finely minced lean meat; scraped beef; the soft part of raw oysters; soft crackers, with milk or broth; soft puddings, without raisins; soft toast, without crust; blanc mange, wine jelly, apple sauce, and macaroni."

I should be disinclined to allow ice-cream, apple-sauce, minced meat, scraped beef, or even soft toast, while there is fever.

ing of the symptoms in every particular. Delirium and stupor are scarcely known. The dry tongue is very much more infrequent, and diarrhea rarely demands other treatment. In the majority of cases I give no medicine, but do not hold myself bound to such course, meeting whatever symptoms seem to demand it by appropriate treatment. For a time I used to give the patient a little whisky and water during the bath. Recently I have discontinued this, unless there seems some special reason for it. There is, however, no harm in it, and it serves to entertain and comfort him. I do not give a preliminary

Fig. 4.—Chart Contrasting the Drop in Temperature after the Bath Early and Later in the Disease.

dose of calomel, as recommended by some, as there seems nothing gained by it.

None of the complications except hemorrhage from the bowels is allowed to interfere with the carrying out of this treatment, nor is menstruation or even pregnancy. The baths are discontinued during hemorrhage, lest the necessary movements of the body should re-excite it; but with the portable bath-tub to be described there need be no interruption even during hemorrhage, should the baths be indicated by the temperature. It is not claimed that the baths shorten the illness, they simply milder it. While it is

probably true of typhoid fever, as of pneumonia, that it may abort spontaneously, we cannot cause it to abort by any means we possess.

In private practice the difficulties of the Brand treatment are greatly increased—unfortunately, sometimes are insuperable. They consist chiefly in the difficulty in arranging the bath and the strain on the attendants. By means of a portable tub devised by Dr. A. H. Burr, of Chicago, a very large part, if not the whole, of these difficulties is removed. Dr. Burr's tub consists, first, of a large rubber sheet, with rings attached near its margins by elastic tapes; second, of a light wooden crib, with fastenings along the lower rail by which to attach the sheet. This frame folds by two movements into a compact bundle. The accessories are a siphon-shaped piece of hose and a

Frame Opened.

Bath-tub Completed, Showing Siphon for Drawing off the Water.

Fig. 5.—Burr's Portable Bath-tub.

bath thermometer. In using, the sheet is first slipped under the patient, brought up over the pillow, and tucked up alongside of the body. The frame is unfolded and placed down over the patient, resting on the mattress, and surrounding patient and pillow. The edges of the sheet are then drawn up and over the top rail of the crib down to the lower rail, and fastened by its rings. This completes a light and perfect tub, capable of holding twenty gallons of water. It can be emptied by the siphon in four minutes (See Fig. 5).* If the ordinary tub be used,—and in hospital service this is usually more convenient,—the same water, if it remains unsoiled by discharges, as it should, may serve for several baths.

Other Methods of Reducing Temperature.—As contrasted with the Brand bath, other methods of securing the good effects of hydrotherapy seem trifling; yet, as it may be impossible to carry out this treatment, such methods must be considered. Sponging is one of the most usual, and if rightly carried out may be quite efficient. It should be resorted to, as is the bath, when the temperature exceeds 102° F. (39° C.), and continued for fifteen minutes, or until the temperature falls. An important condition of success—

* The Burr bath-tub is sold by E. H. Sargent & Co., 106 Wabash Avenue, Chicago, Ill. Another tub, as convenient and as easily managed, has been devised by Dr. S. Clifford Boston, who dispenses with the framework, substituting strong iron supports, made by Jones, Leopold & Co., southwest corner Ridge Avenue and Fairmount Avenue, Philadelphia.

ful sponging is often overlooked. A thin film of water should be left on the surface sponged, as it is the evaporation of this, rather than the temperature of the water, which is effectual in cooling the body. Temperatures that cannot be thus controlled can often be kept down by a partial wet-pack, which I have found very efficient: The patient's trunk is enveloped from the axilla to the thighs in a folded sheet, which is kept constantly wet, or as much so as is required to control the temperature, by the continual addition of cold water.

Antipyretics, including antipyrin, antifebrin (acetanilid), phenacetin, and others of the same class, which act by producing copious perspiration, are no substitutes for the baths, for, while they reduce temperature, their effect is but temporary, and their continuous employment too depressing to the patient. Moreover, they are purely antipyretic, and lack the tonic influence to the nervous and muscular systems which characterizes the cold tub-baths. Quinin, formerly used in massive doses for its antipyretic effect, has been replaced by the more modern agents.

Guaiaicol, locally applied, is undoubtedly an efficient antipyretic, and has a warm advocate in Horace G. McCormick in the treatment of typhoid fever. After washing the skin, from one to ten minims are rubbed into it, and the part covered with oiled silk. The fall in temperature is prompt. Some rather alarming symptoms of collapse are, however, reported from its use, and it has failed to secure a permanent footing.

The Expectant-Symptomatic Treatment.—Where the difficulties in the way of the Brand method are insuperable, I prefer to place the patient in bed on the diet described, combat the temperature by sponging or wet-packs, and for the rest adopt what may be termed the expectant-symptomatic method, meeting the symptoms as they arise in accordance with the following:

(a) *Indications for Alcohol and Other Stimulants.*—I prefer to reserve alcohol until called for by signs of waning strength. That it is a remedy of the greatest value I fully admit, but it is also true that mild cases may be carried to a favorable termination without it. On the other hand, I favor its liberal use when needed, giving sometimes as much as an ounce (30 c. c.) of whisky or brandy every hour, though such doses are rarely needed. More frequently, a half ounce (15 c. c.) every four or two hours is quite sufficient, even where there is considerable adynamia. A low, muttering delirium, feeble, dicrotic pulse, and dry tongue are among the indications which imperatively demand alcohol; a high temperature does not contra-indicate it, as an antipyretic effect also follows the use of large doses, and delirium is sometimes calmed by it. Other diffusible stimulants which may be used in conjunction or alternation with alcohol are the aromatic spirit of ammonia and the carbonate of ammonium, while digitalis and strychnin may tide a feeble heart over a period of weakness. From five to ten minims (0.333 to 0.666 gm.) of the tincture of the former, and 1-30 to 1-20 of a grain (0.00216 to 0.00324 gm.) of the latter may be given as demanded, while their hypodermic use may be availed of. At the Hospital of the University of Pennsylvania we have found hypodermic injections of camphorated oil 1 grain (0.066 gm.) to 15 minims (1 gm.) very useful in tiding over extreme adynamia. The injections may be repeated once in four hours or oftener.

Transfusion or, what is more practicable and as efficient, hypodermoclysis of normal salt solution (0.8 per cent. sodium chlorid) may be availed of in the extreme adynamia which sometimes attends protracted typhoid fever.

(b) *Treatment of Special Symptoms.*—Methods more directly adapted to control *delirium* are an ice-cap to the head, the bromids, spirit of chloroform, chloral, and Hoffmann's anodyne. With the cold-bath treatment they are rarely necessary. Occasionally, meningeal symptoms are so violent that leeches may be used to the temples or behind the ears. I have seen an almost magically quieting effect thus produced. Blisters are useless.

Little difficulty is commonly experienced in controlling the *diarrhea* of typhoid fever. As stated, with the cold bath treatment very little special treatment is necessary. Simple preparations of opium, either alone or in combination with bismuth or nitrate of silver or acetate of lead, or salol, are usually sufficient. Specific action has been claimed for nitrate of silver. I have not been convinced of this, yet it is, in combination with the extract of opium, 1-4 of a grain (0.0162 gm.) of each, my favorite remedy for the diarrhea. Similar specific effect, more particularly in healing the ulcers, has been claimed for the oil of turpentine. The impression made by the teachings of the late George B. Wood on the profession of the United States as to this effect has not yet been effaced. He held that the dry, leathery tongue so often presented in this disease is the indication for its use. Whether such view was correct or not, few who have used the oil of turpentine have failed to see the coated tongue clear up under its use. Turpentine is also useful as a stimulant. It should be administered in doses of ten minims (0.66 gm.) in mucilage of acacia every six or eight hours.

Constipation, especially during convalescence, is not infrequent, and should not be too hastily interfered with. If it is necessary to interfere, it should be by simple enema only. Aperients by the mouth in this stage are dangerous, and I am confident I have seen at least one life sacrificed by purgatives thus administered, having been succeeded by perforation, peritonitis, and death. On the other hand, indifference to the condition of the bowels sometimes leads to fecal impaction, which can only be relieved by the finger. Such a state of affairs should be averted by watchful care.

Hemorrhage from the bowels should be treated by absolute quiet with cold to the abdomen. Food should be reduced to a minimum and should be of the blandest character, as represented by peptonized milk and liquid beef-peptonoids. The administration of food may be suspended for some hours without risk. In severe cases the foot of the bed should be raised, and a hypodermic injection of 1-8 to 1-4 of a grain (0.008 to 0.016 gm.) of morphin given at once. In such cases, where prompt and decisive action is necessary, a syringe of a filtered fluid extract of ergot may be injected hypodermically, and repeated later, if necessary, in half the dose. In mild cases astringents, such as tannic acid or gallic acid and the acetate of lead, may be given by the mouth, the former in doses of 10 to 15 grains (0.666 to 1 gm.) hourly until some hours have elapsed without a hemorrhage. The acetate of lead should be given in one to three grain (0.066 to 0.194 gm.) doses every three hours, combined with extract of opium, 1-4 of a grain (0.016 gm.). Turpentine is highly valued by some in the treatment of hemorrhage from the bowels. In cases of extreme weakness ether and digitalis may be given hypodermically.

Tympanitic distention of the abdomen is often a distressing symptom. It is usual to treat it with turpentine in ten-minim (0.666 gm.) doses every four to six hours. The rectal tube should be cautiously used if the meteorism is great, and large quantities of gas are sometimes thus disengaged from

the large intestine. The quantity of food should also be reduced to a minimum, as its fermentation and decomposition contribute to the gas.

Pain induced by meteorism or otherwise may be allayed by turpentine stupes over the abdomen, though sometimes it may be necessary to reinforce the stupes by small doses of opium, or a light, warm poultice may be substituted. Sudden, sharp pain, similar to that produced by tympanitic distention of the bowel, is also caused by *peritonitis*, of which tympany is likewise a symptom, and the two often occasion many anxious moments to the physician necessarily in doubt as to whether this serious complication may occasion them. If a peritonitis is the result of extension of inflammation by continuity and not of perforation,—a possible condition,—recovery may take place. Such recovery is favored by absolute rest of the bowel, best secured by hypodermic injection of morphin, 1-4 grain (0.016 gm.), repeated if necessary. Even such movement as is necessitated by the use of the bed-pan is of questionable propriety. It is much better to permit the discharges to pass into a soiled sheet.

Perforation is the most serious accident which can happen to the typhoid fever patient, though it is claimed that recovery has taken place where peritonitis has been thus caused. Indeed, according to Murchison, 10 per cent. of all cases recover, 5 per cent. if general peritonitis supervenes. Even this seems a large proportion, for in my experience no case of undoubted perforation has recovered. On the other hand, recent results after operation have been so favorable as to make it imperative that the propriety of this treatment should be considered in each case. It is important to remember that early operations are those attended with largest success. In a recent and exhaustive paper ("Jour. Am. Med. Assoc.," January 20, 1900) on the "Surgical Treatment of Perforation of the Bowel in Typhoid Fever," W. W. Keen collected 158 cases and summarizes as follows:

OUT OF 158 CASES OF OPERATION FOR PERFORATION.

When Done.	Total.	Died.	Recovered.	Percentage of Recoveries	
Within 4 hours, . .	8	6	2	25	} 19.44
In 4 to 8 hours, . .	12	11	1	8.33	
In 8 to 12 " . .	16	12	4	25	} 30.76
In 12 to 18 " . .	25	17	8	32	
In 18 to 24 " . .	14	10	4	28.57	
After 24 hours, . .	44	38	6	13.63	} 29.09
Not given,	39	27	12	30.74	
Total,	158	121	37	23.41	} 25.33

Keen also formulates the rule that *if the operation is not done within about twenty-four hours after the perforation, there is probably no hope of a recovery.* A surgeon should therefore be immediately called, and if collapse is not too profound laparotomy should be done.

For *sleeplessness* the milder soporifics usually answer; 10 to 15 grains (0.666 to one gm.) of sulphonal generally furnish the required rest. Chloramid 30 grains (two gm.), trional 15 to 30 grains (one to two gm.), or chloral 10 to 15 grains (0.666 to one gm.) may be used. If these remedies are insufficient, morphin must be used, 1-4 grain (0.016 gm.) being given by the mouth or half as much hypodermically, or more if necessary.

Bed sores can generally be averted by scrupulous attention to cleanli-

ness, the thorough drying of the patient after washing, removing thus traces of urine or other discharges, and by sponging the patient daily with alcohol or whisky. Above all, his position in bed should be frequently changed and all inequalities in the bed clothing should be smoothed out, while the bed should be kept clear of crumbs and other irritating particles. Should a sore appear it must be antiseptically dressed, while the part should be protected from pressure by pads and air-cushions.

For *hiccough* the more ordinary measures commonly effectual are counter-irritation by mustard, dry cupping, or blistering; the various anodyne measures, including Hoffmann's anodyne, chloroform, and the hypodermic injection of morphin. The anti-spasmodics, including sumbul, the oil of amber, and especially musk, have been useful. *Cannabis indica* is also recommended. In an obstinate case under my care after all measures had failed, including musk, the hypodermic injection of one grain (0.06 gm.) of camphor dissolved in oil, 15 minims (0.5 gm.) repeated hourly, relieved the case in six doses. A second case has been relieved in the same hospital by like treatment. In other cases I have found musk useful when all else failed, but it is a most costly remedy and its use is thus necessarily limited. The dose is 5 to 10 grains (0.3 to 0.6 gms.).

The *cystitis* sometimes present in typhoid fever is commonly easily relieved by washing out the bladder with boric acid solution, say a dram (4 gm.) to a pint (0.5 liter) of sterilized water; or instead of this salol may be given in five-grain (0.3 gm.) doses four or five times a day, as a urinary antiseptic. The best remedy is urotropin, which is a derivative of formaldehyd and is said to be non-toxic and non-irritating. According to Mark W. Richardson daily doses of 30 grains (2 gm.) will remove typhoid bacilli permanently from the urine in a week.

The Management of Convalescence.—In no disease is watchfulness during convalescence more important. The effect of indiscretion in diet in producing relapse and recrudescence has been referred to. But there are other dangers during convalescence. It is to be remembered that the complete healing of intestinal ulcers is often delayed after all other symptoms have disappeared except a slight elevation of temperature; that a deep-seated ulcer may thus remain with the thin peritoneum for its floor, rendered weaker by reason of imperfect nutrition. Such a membranous floor is known to have been torn by simply reaching over for a book and to be followed by a fatal peritonitis. These are reasons, too, for putting off the use of solid food until the temperature has maintained the normal for a considerable time, certainly a week. Then the diet should be changed most gradually, first permitting a soft-boiled egg or poached egg in the morning, and awaiting developments. If no fever follows, it may be continued daily. The next step is to allow some thoroughly softened milk toast, then a small quantity of well-boiled rice, with a suitable interval after each first trial until sure that no harmful results follow. Finally, tender meat may be allowed, and then soft vegetables one after another.

Emotional disturbance is a well-recognized cause of recrudescence, and should be carefully guarded against.

I have already referred to constipation and the importance of correcting it by enemata only.

During convalescence the *hair* is very apt to fall out, but usually returns in a natural way. It may be desirable to cut it close, though scarcely necessary to shave the head, as some recommend.

Special Forms of Treatment.

The Antiseptic Treatment.—The antiseptic treatment of typhoid fever is based upon the idea of destroying the germs of the disease in the intestinal canal, and thus cutting off their harmful influence. If I mistake not, it is not claimed that it is possible to destroy the bacilli elsewhere in the economy—that is, in the blood, the spleen or other lymphatic tissues, or wheresoever they may be present. In addition to the localized effect on the specific bacilli in the intestine, this treatment claims also to arrest fermentation and check the activity of the commoner intestinal bacteria, which, it is alleged, are fanned into virulence by the presence among them of typhoid bacilli. The claims of the adherents of the method do not altogether agree, but its more moderate supporters hold only that it renders the disease milder and diminishes its mortality, urging it more particularly in those cases where for any reason the Brand treatment cannot be carried out.

Among the remedies employed for their antiseptic effect are calomel, betanaphthol, carbolic acid, chlorin water, naphthalin, salol, and tincture of iodin. *Calomel* has long been used by various physicians in the treatment of this disease. Its popularity is partly due to the fact that it is also an excellent and safe laxative. It had the early support, in the treatment of typhoid fever, of Liebermeister, who claimed that under its use the duration of the disease was shortened and its intensity lessened. His plan was to give three or four doses of 7 1-2 grains (0.5 gm.) each, in the first twenty-four hours of treatment. I have said that some of the supporters of the Brand treatment prefer to precede that treatment by such a dose of calomel. It can certainly do no harm. *Betanaphthol* is another efficient and non-toxic germicide. It is held that doses sufficient to produce an antiseptic effect are not irritating. These doses are 5 to 10 grains (0.33 gm. to 0.66 gm.) three times a day in a wafer, capsule, or tablet. It is sometimes combined with salicylate of bismuth if there be diarrhea, or salicylate of magnesium if there be constipation, as suggested by Bouchard. All the advantages of this treatment are claimed for it, including diminished abdominal pain, diminished meteorism, a clean and moist tongue, inodorous stools, rapid convalescence, and less tendency to secondary complications.

Another one of these remedies is a *compound of carbolic acid and iodin*,—1 part of the former and 2 of the latter,—given in doses of 1 to 3 drops, well diluted, three to six times a day. *Chlorin* water is also an old remedy recommended by Sir Thomas Watson and by Murchison, and recently revived in the treatment of typhoid by Burney Yeo, who claims that it cleans the tongue quickly and removes the fetor of the evacuations within twenty-four hours; that it reduces the temperature and shortens the attack; while the physical strength and mental clearness of the patient are maintained, together with a greater power of assimilating food and, consequently, rapid and complete convalescence. Yeo even claims a general antiseptic influence for this treatment. He adds to 12 ounces (360 c. c.) of chlorin water, 24 to 36 grains (1.584 to 2.376 c. c.) of quinin and an ounce (30 c. c.) of syrup of orange-peel, and gives an ounce (30 c. c.) every two, three, or four hours, according to the severity of the case.

Salol is recommended for the same antiseptic purpose; 40 to 50 grains (2.5 to 3.25 gm.) in the twenty-four hours, in capsules, wafers, or tablets, in doses of 5 to 10 grains (0.3 to 0.66 gm.). *Thymol* is recommended in

the same doses. All these doses in my judgment are so large that I fear their harmful effect would more than equal any possible advantage.

The Eliminative and Antiseptic Treatment.—This treatment is intended to add to the antiseptic effect a prompt removal from the bowels of the bacillus and its toxic products. The first it is sought to accomplish on the principles previously described; the second by thorough daily evacuations of the bowels by means of purgatives, large quantities of fluids being given at intervals to replace the liquid carried off in the discharges. This treatment is especially associated with the names of Woodbridge, of Cleveland, and Thistle, of Toronto. The former published a book on "Typhoid Fever and its Abortive Treatment," in which he claims that if this treatment is instituted sufficiently early, not only is the disease aborted, but the patient need not go to bed or be restricted in diet, debarred from social enjoyment, or even be required to neglect or omit his business. Without commenting further upon these claims, I will state that a trial of the Woodbridge treatment was made during 1898 and 1899 in the wards of the New York hospitals and the United States Army Hospital at Fort Meyer, Va. Of 14 cases treated in New York 4 were under the personal care of Dr. Woodbridge. Thirteen cases recovered and 1 died, the fatal case being one under Dr. Woodbridge's personal care. The cases were treated with antiseptic and purgative tablets prepared by Parke, Davis & Co., according to Dr. Woodbridge's formulæ.* The remaining cases were treated at Fort Meyer by Dr. Woodbridge. Of these, 4 patients died, 3 of intestinal hemorrhage and 1 of exhaustion, giving a mortality of 10.5 per cent. for the 38 cases, as compared with the rate of 9 per cent. among the cases treated in the other wards of the hospital.

Thistle's method is much simpler and more easily carried out. Calomel is given daily in fractional doses, 1-2 grain (0.033 gm.) every half hour, until three grains have been taken, followed three hours later by Epsom or Rochelle salts in half-ounce (15 gm.) doses, sufficient being given to secure from 3 to 5 movements daily. To compensate for the withdrawal of so much fluid from the body as well as to eliminate the poison through the kidneys, the ingestion of large quantities of water is enjoined. For intestinal antiseptics salol is given in five-grain doses, every three hours, with 8 ounces (236.56 c. c.) of water. Thistle is not so extravagant in his claims as Woodbridge, alleging, however, that hemorrhage and perforation are both more infrequent. He reports in a recent paper 172 cases treated by himself and other physicians in Toronto, with 5 deaths—a mortality of 3 per cent. Of the fatal cases 2 died of pneumonia in early convalescence, 2 of intestinal hemorrhage, and 1 of hemorrhage from the stomach and nose with general purpura in all parts of the body.

In view of the fact that typhoid fever is a general and not a local infec-

* The formulæ are three in number, designated No. 1, No. 2, and No. 3. No. 1, a tablet, contains podophyllin resin, 1-060 grain; calomel, 1-16 grain; guaiaccol carbonate, 1-16 grain; menthol, 1-16 grain; eucalyptol, q. s. Immediately on the appearance of fever, and before the diagnosis is made, one of these tablets is given every fifteen minutes during the first twenty-four hours, and in larger doses, if necessary, in the second twenty-four hours, until not less than five or six evacuations are secured each day. On the third or fourth day tablet No. 2, consisting of the same ingredients in precise proportion, with 1-16 grain thymol added, is given every one or two hours at first, the size and frequency of the dose of both tablets being regulated to allow the movements to become gradually less frequent until the temperature drops to normal and the passages are reduced to one or two a day. On the fourth or fifth day, formula No. 3, composed of guaiaccol carbonate, gr. iij, thymol, gr. j, menthol, gr. ss, eucalyptol, *m. v.*, in capsule, is given every three or four hours, alternating with the tablet. The medicine is to be washed down with copious draughts of distilled or, if necessary, some laxative or diuretic mineral water.

I am indebted to the admirable paper, by John Winters Brannan, on "Typhoid Fever," in vol. xvi, of the "Twentieth Century Practice of Medicine," for the facts here presented on the antiseptic and eliminative treatment of this disease.

tion and that the local lesions in the bowel are only a part of the local manifestation, the antiseptic and eliminative treatment does not seem to rest on a thoroughly rational basis, while the extravagant claims, especially of Woodbridge, discredit his results. These claims have finally been overthrown by his own experience in New York City and at Fort Meyer. On the other hand, it does seem reasonable that sloughing and extensive ulceration in the bowel may cause secondary sepsis. Toward an effort to prevent such infection the antiseptic treatment may, therefore, be permitted if the dosage be not excessive and otherwise harmless to the patient; but not with a view to eliminating the poison. Theoretically, one might object to purgation by calomel, because the unloading of the gall-bladder may be attended by a copious discharge of bacilli capable of reinfecting the bowel.

Serum Treatment of Typhoid Fever.—The practical studies and application of the serum treatment by Dr. A. E. Wright, of Netley, and his pupils, and of Chantemesse in Paris, have given a decided impulse to this method of treatment because of the seemingly satisfactory results obtained. These results include immunity as well as cure. Of the several methods of procedure, Wright adopted that of inoculating the subject with measured quantities of dead, but still poisonous, micro-organisms. He prepared an antityphoid vaccine from agar cultures of typhoid bacilli, grown for 24 hours at blood heat. The cultures thus obtained are emulsified by the addition of measured quantities of sterile broth. The resulting emulsion is sterilized by raising it to a temperature of 140° F. (60° C.) and keeping it at that temperature for five minutes.

The local and constitutional symptoms succeeding the injection of the vaccine vary in degree with the dose used. Local symptoms include tenderness two or three hours after injection at its site, gradually increasing in severity and extending upwards into the armpits and downwards into the groin. There is also commonly seen a patch of congestion about the site of inoculation with red lines of inflamed lymphatics, extending upwards into the armpits. These symptoms disappear about 48 hours after injection. Constitutional symptoms include some degree of tenderness, beginning generally two or three hours afterwards. There is loss of appetite, while nausea and even vomiting may supervene. Rest is disturbed and there is some fever in all cases. These symptoms also pass away in a couple of days. In three only out of eleven cases tested did the health seem to be shaken for three weeks.

As was to be expected, the blood of persons thus inoculated was found to immobilize and agglutinate the typhoid bacilli. Moreover, Wright's observations go to show, in harmony with those of Pfeiffer, that the immunity acquired by undergoing an attack of actual typhoid is not greater than that which is acquired by an inoculation of typhoid bacilli. There are, however, limitations the consideration of which is scarcely in place in a text-book, and the student who is further interested is referred to the admirable papers by Wright upon this subject.*

A summary of the statistics prepared by Prof. Wright as to results of antityphoid inoculation † in India, South Africa, and England, go to show, 1st, a decided reduction of incident cases in the inoculated; 2d, a reduced death-rate in the inoculated who acquired the disease as contrasted with the uninoculated who acquired the disease; 3d, that the duration of immunity

* "Remarks on Vaccine against Typhoid Fever," by A. E. Wright, M. D., and Surg.-Maj. D. Semple, M. D. "British Medical Journal," January 30, 1897.

† The "Lancet," September 6, 1902, page 256.

thus obtained varies from five months to two years, as determined by the duration of the agglutinative reaction; 4th, that double (successive) inoculation is more efficiently protective than single inoculation. In a letter received from Professor Wright while printing this edition he says he usually commences with 500,000,000 typhoid bacilli and gives ten days later 1,000,000,000 dead typhoid bacilli. He also writes that he never attributed any curative value to antityphoid inoculations.

In France Chantemesse has prepared an antityphoid serum, as contrasted with the antityphoid vaccine, which he claims to be curative and prophylactic. In his latest publication* he shows from a review of the statistics of the various hospitals of Paris, excepting that under his own direction, a combined mortality of 19.3 per cent., and that, while there were natural variations, the lowest recorded mortality in any hospital exceeded 12 per cent. Under the serum treatment, which had been received by 356 patients up to the time of his report, only 17 died, a mortality of 4.7 per cent. At Toulon, out of 151 patients 13 died, the addition of this mortality making 6 per cent., as contrasted with the German Army statistics, which gave a mortality of 9.5 per cent. It may be mentioned in passing that the reduced mortality thus claimed is but 1.4 per cent. less than that obtained by the tub-bath treatment by physicians in the United States.

In this country Drs. William Royal Stokes and John S. Fulton,† following Abel and Loeffler, produced an antityphoid serum by injecting gradually increasing doses of a 48-hour-old virulent culture obtained from the Johns Hopkins Hospital Laboratory into the subcutaneous tissues of the abdomen of the hog, which was subsequently bled, the serum drawn and trikresolized. It was found that guinea pigs given subcutaneous injections of this protective serum were rendered immune against a peritoneal injection of a virulent typhoid bacillus. More precisely, that a *subcutaneous injection* of the serum in doses of from 1-600 to 1-800 of the body weight will protect guinea pigs against four times the minimum fatal dose of intraperitoneal injection with the typhoid bacillus. The injection of 1-3000 to 1-4000 of the serum by weight into the *abdominal cavity* will protect against five times the minimum fatal dose, and a dose of 1-600 to 1-800 of the body weight will protect against seven times the minimum fatal dose of the typhoid bacillus. Thus far only 18 cases have been treated by Drs. Stokes and Fulton's serum, and although they admit that so few cases lead to no conclusion and perhaps no very reasonable inference, they are encouraged to continue their experiments and think they have shortened the duration and intensity of the fever in most of the cases, while none were lost.‡

Prophylaxis.—Most important in the management of typhoid fever is the *disinfection of the excreta*, which are the contagium bearers, through the careless handling of which the disease is communicated to others. The same is perhaps true of the vomited matters.

Among the most suitable disinfectants, on account of its cheapness, harmlessness, and effectiveness, is *chlorinated lime* or bleaching powder, also called chlorid of lime, which contains from 25 to 40 per cent. of

* "Presse Médicale," December 24, 1902.

† "Maryland Medical Journal," August, 1902.

‡ In explanation of the imperfect results thus far obtained by antityphoid sera, allusion should be made to the observations of Ehrlich, Bordet and Wasserman to the effect that bacteria are destroyed in artificial immunity by the joint action of two distinct substances, one the intermediate or immune body produced in the blood when animals are immunized by the injection of non-fatal doses of various bacteria. The second is called the complement or end body, and is a sort of digestive ferment always present in the blood. It is destroyed by a temperature of 60° C. (160° F.) while the immune body is not.

available chlorin. A solution made in the proportion of 4 to 100 of water, containing, therefore, at least 1 to 1.5 per cent. of chlorin, is sufficiently strong. Some of the solution is placed in the chamber vessel before it is used, and the remainder, in all say a pint, is added afterward. Thorough admixture should be made, and an hour allowed to elapse before the stool is thrown into the privy well or water-closet, if disposed of thus. In the country the disinfected stool may be buried. Solution of chlorinated *soda*, or Labarraque's solution, is a more elegant but not more effective disinfectant. As it contains about 2 per cent. of chlorin, it is nearly equivalent, when undiluted, to the above solution of chlorinated lime. Chlorinated lime rapidly loses its chlorin, and should be kept in tight vessels.

Carbolic acid, in the proportion of one part of the commercial acid to ten of water, is an efficient disinfectant for this purpose. The same method as that described for chlorinated lime must be employed, and an exposure of twenty minutes to half an hour maintained. Quite as good a disinfectant for intestinal evacuations is *milk of lime* or ordinary "whitewash," composed of lime in solution and in suspension. This should be thoroughly mixed with the evacuations until the mass is distinctly alkaline, and should remain in contact for one or two hours, since it is slower in its action than chlorinated lime or carbolic acid, and much longer exposures are required to destroy the bacillus. It is particularly adapted to the disinfection of privy wells and latrines, into which it may be thrown, freshly prepared in the proportion of 1 part by weight of recently burned calcium hydrate to 8 of water, or about 12 per cent. It is not harmful to water-closet pipes in such quantities as required to disinfect the stools of a single case of typhoid fever.

Acidulated *solution of corrosive sublimate* 1 to 500 is an admirable disinfectant for stools, but is not altogether harmless to plumbing, whence it is less satisfactory when excreta are thrown into city water-closets.

Sulphate of iron or copperas is a good antiseptic and deodorant, but not a true disinfectant. An antiseptic prevents the growth of bacteria without necessarily killing them, while disinfectants do both. Above all, it must not be forgotten that simple hot water thoroughly mixed with the fecal discharges is an efficient disinfectant.

Most important in the prophylaxis of typhoid fever is *drainage*. It seems to be now definitely settled that the fever originates in every instance from the ingestion in some way of the typhoid bacillus commonly in drinking-water or milk, or in food contaminated with it, more rarely by inhalation. Hence, it is of the greatest importance that the sources of water used in domestic economy should be protected against contamination by discharges containing the specific bacilli, which sometimes find their way into wells and other sources of water-supply.

Nurses should be enjoined to guard against their own infection by due attention to cleanliness after caring for the discharges of a patient and even after tubbing, while watchful care should be taken not to carry the hands to the mouth during the bath. On the other hand, the infection is one of the easiest controlled, and the spread of typhoid fever can be effectually prevented if the precautions advised are followed. Moreover, it cannot be too strongly insisted upon that any infected water or milk may be rendered thoroughly harmless by boiling and filtration. Physicians should lose no opportunity to inculcate this truth as well as that limpidity of a water does not guarantee its innocuousness, while it may even be slightly turbid and yet harmless. Boiling is the most important treatment, far more important than filtration.

PARATYPHOID FEVER.

Definition.—A form of infectious fever presenting a clinical picture identical with that usual to typhoid fever, but due to a bacillus whose characteristics are intermediate between the typhoid and colon groups, and called therefore, the paratyphoid or paracolon bacillus.

Symptoms.—The symptoms are those of typhoid. Differences observed are, in general, greater mildness and more favorable prognosis; greater frequency of diarrhea and more frequent termination of fever by crisis. Myositis and purulent arthritis, very rare in typhoid fever, are among the complications. Absence of intestinal ulceration is characteristic. The disease does not respond to the Widal test, but the serum reacts upon fresh cultures of the paracolon or paratyphoid bacillus.

Treatment is in no way different from that of typhoid.

MOUNTAIN FEVER.

SYNONYM.—*Rocky Mountain Fever.*

Definition.—A form of fever met in the mountain regions of Western United States, characterized by its moderate temperature, 101° to 103° F. (38.2° to 39.3° C.), a duration of from two to four weeks, and generally mild course.

Mountain fever has come to be pretty generally acknowledged as a variety of typhoid fever, modified by the combined factors which go to make up the influence of high altitudes. Certain it is that if a careful study of the cases reported by various observers is made, the clinical picture differs no more from the typical picture of typhoid fever than the abortive forms of typhoid occurring at low altitudes. It must be admitted, however, that this view is not unanimous, and it should be mentioned that Surgeon Charles Smart,* of the United States Army, in a careful review of the subject, in 1878, in a paper entitled "On Mountain Fever and Malarious Waters," concluded the disease was typho-malarial fever. Such a view implies a separate specific disease, typho-malarial fever, which is not admitted at the present day by the best authorities. The lesions of typhoid fever in the ileum have been found in at least two of the very few fatal cases reported. † An enlarged spleen is also found. Finally, Woodruff's ‡ studies of the serum reactions in this form of fever have furnished all necessary proof of the identity of the disease with typhoid fever.

Epistaxis occurs. So far as I am aware, however, no spots have been reported except a "doubtful *tâche rouge*" by Roland G. Curtin § in one of four cases seen by him in 1868 in Wyoming Territory. Diarrhea has been noted, but there is a tendency rather to constipation—not infrequently the case in typhoid fever. Tympanites also occurs. The other symptoms are those incident to all fevers, such as debility, headache, and frequent pulse.

Doubtless many imperfectly studied instances of other forms of disease are classed by indifferent observers as mountain fever, as in a case mentioned by Curtin.

* "Am. Jour. Med. Sci.," January, 1878.

† One is reported by Surgeon Hoff, U. S. Army, "Am. Jour. Med. Sci.," January, 1880; the specimen from another is in the United States Army Medical Museum, Washington D. C.

‡ Woodruff, C. E., "The Form of Typhoid Fever Called Mountain Fever; Widal's Test; Afebrile Cases," "Jour. Am. Med. Assoc.," 1808, vol. xxx, p. 753.

§ "Rocky Mountain Fever." Reprint from the "New York Med. Jour.," January 8, 1837.

Mountain fever is not to be confounded with *mountain sickness*, another condition incident to unusual exertion at high altitudes. In it there are dyspnea, frequent pulse, dizziness, and bleeding at the nose; also great prostration on exertion, and sometimes slight elevation of temperature.

Treatment.—The treatment of mountain fever, mainly symptomatic and roborant, would be, so far as any special measures are needed, that of typhoid fever.

TYPHUS FEVER.

SYNONYMS.—*Typhus Exanthematicus; Petchial Fever; Pestilential or Putrid Fever; Ship Fever; Jail Fever; Camp Fever.*

Definition.—An acute, highly contagious fever, favored by closely crowding human beings; especially characterized by sudden onset of high fever, by a petechial eruption, typhoid symptoms, and short duration as compared with typhoid fever; terminating suddenly at the end of the second week.

Historical.—It is commonly conceded that the plague of Athens, so graphically described by Thucydides (B. C. 470 to 400), was the same as the typhus fever of to-day, though it has also been held identical with the Oriental or bubonic plague, which, like typhus, until recently has been regarded as growing very rare. It is also possible that what is so often mentioned in the Scriptures as pestilence may have been typhus, although this too may have been Oriental plague. The same is true of numerous epidemics which prevailed during the first fifteen hundred years of the Christian era, many of which were undoubtedly typhus, especially in Spain and Italy. Among the names were *La Pourpre* in French, *Tabardiglio* in Spanish, *Petecchie* in Italian, *Fleckfieber* in German, all of which meant "spotted." It was called pestilential, putrid, malignant, petechial, and "jayl" fever in England, and also "the plague" until 1760, when the name typhus was given it by Sauvages. The history of its separation from typhoid was given under that disease.

Etiology.—Though of acknowledged infectious nature, no organism has as yet been isolated that can be held responsible for typhus fever,* but several non-distinctive bacilli have been isolated from the blood and tissues of patients. Fostered by close crowding, filth, and famine, it each year becomes more infrequent as the conditions favoring it are eliminated, and there is reason to believe it will ultimately be stamped out. Thus, in 1897 there were only three cases in all the London fever hospitals. Ireland has been its home for centuries, but filthy and crowded sections and the almshouses of large cities have at different times furnished seats for its lodgment. My own experience with the disease is limited to two mild epidemics in the Philadelphia Hospital in 1866 and 1883, and another quite serious in the Camden County (New Jersey) Almshouse in the winter of 1880-81. Quite a serious epidemic prevailed in New York City in 1881-82, and a milder one in 1892-93. Sporadic cases rarely occur, but its spontaneous origin is scarcely possible, though such possibility was admitted by Murchison, whose judgment on fevers was at one time regarded as almost infallible.

Typhus fever is eminently contagious, and cases should be promptly isolated. Nurses and others in constant attendance upon typhus patients are more liable to be attacked than those who, like the physician, merely visit them daily, although perhaps no disease in the past has included among its victims so many medical men. It is not known precisely what the contagium bearer is. It may be all the exhalations and discharges from the body, but it is not especially the bowel discharges.

* For a summary of the observations thus far made on the "Micro-organisms in Typhus Fever," see a paper with this title by J. B. Byron and Egbert Le Fevre, in vol. ii., "Researches of the Loomis Laboratory," New York, 1892, p. 130.

Morbid Anatomy.—As to the morbid anatomy of this disease, there is really nothing distinctive. Rigor mortis is apt to be delayed. The petechial eruption remains after death, and gangrenous bed-sores may be found on the body. The most constant lesion is *moderate enlargement of the spleen*, and in this enlargement the *liver* and *kidneys* may share, and their cells be the seat of cloudy swelling due to fever heat. Indeed, all the tissues, including the heart muscle, may be granular from this cause. The splenic enlargement is mainly due to vascular engorgement, but there may also be some hyperplasia of lymph-cells. The lymph-follicles of the intestine may be enlarged from the same cause, but there is no ulceration of these or of Peyer's patches. The blood is dark and liquid. Hypostatic congestion of the lungs is very frequently found; likewise bronchial catarrh. The permanence of

Fig. 6.—Temperature in Typhus fever ("Pepper's American Text-book of Medicine.")

the eruption after death is in strong contrast with that of typhoid fever, which disappears after death.

Symptoms.—The *period of incubation* is usually about twelve days. It may be less. There is seldom any prodrome, the *invasion* being *sudden*, announced by a *chill* or *chills* followed by headache and great *muscular pain*, especially in the back, and by *high fever*, the temperature rapidly rising to 103°, 104°, 105°, and 106° F. (39.4°, 40°, 40.5°, 41.1° C.) without any of the tidal-wave rise characteristic of typhoid fever. The *pulse* is at first full and strong, but soon weakens and becomes frequent—120 and more. There is extreme *debility*. Almost characteristic are the *red, congested conjunctivæ*, the *dusky face*, *dull expression*, and *low, muttering delirium*, which contrasts strongly with the sometimes active delirium of typhoid. The tongue is early coated and becomes rapidly dry. The bowels are constipated.

On the third to the fifth day the *eruption* presents itself; it is of *two*

kinds. The *petechial*, or more characteristic, is at first not unlike that of typhoid fever, but is darker in hue and disappears less readily on pressure; a little later it is barely influenced, and still later does not respond at all to pressure. It has become hemorrhagic, petechial—the blood is without the vessels. There may be spots exhibiting each one of these stages. This eruption is also more scattered than that of typhoid fever, appearing all over the body, while that of typhoid is limited to the chest and belly. In addition to the petechial eruption there is also a peculiar *dark mottling* of the skin, an alternation of purple blotches with others of a light hue, generally capable of being influenced by pressure, but these blotches, too, may become blood extravasations.

With the *beginning of the second week all of the symptoms deepen*: The tongue becomes dry, fissured, and leathery; sordes collect on the teeth; stupor deepens, there are subsultus and nystagmus, *coma vigil*,—the patient is unconscious, but the eyes are wide open,—and picking at the bed-clothes. At this time, too, the peculiar disagreeable odor said to be characteristic of typhus fever makes its appearance. It is variously described: by Gerhard, as pungent, ammoniacal, and offensive; by the late George B. Wood, as like the odor of badly ventilated rooms, in which a number of persons are collected; and by others, as like the odor given off by rotten straw or the urine of mice. Gerhard and Murchison both held that its degree was proportionate to the degree of contagiousness of the case. The breathing becomes more rapid, the pulse weaker, scarcely appreciable, and the patient may die of adynamia; or at the end of the second week a *crisis* occurs, he falls asleep, the temperature declines as rapidly as it rose, and often after a long sleep the patient wakes up refreshed and with a clear head. Convalescence now progresses, and although it may be slow, relapses rarely occur.

A few symptoms require special allusion: First, the *fever*. The skin is burning hot and the temperature rises to 106° F. (41.1° C.), and even 108° F. (42.2° C.) and 109° F. (42.7° C.) toward a fatal termination. It is the *calor mordax*. There is always *hypostatic congestion of the lungs* and, along with this, a great deal of *bronchial catarrh* and *cough*. Such catarrh may pass into a broncho-pneumonia, which may terminate in gangrene of the lungs.

The *urine* is concentrated, as in all high fevers, and urea and uric acid are relatively increased. *Albuminuria* is also common, but there is not usually any organic change in the kidney beyond the cloudy swelling referred to. *Retention of urine* on account of the mental hebetude may occur, and should be guarded against by frequent examination and catheterization. *Bed-sores* are common, and there may even be gangrene of the extremities.

Instances of the ambulatory form of typhus fever are much more rare than of typhoid, but they are occasionally met.

Diagnosis.—How does typhus fever differ from *typhoid* fever? I have referred to the differences in the eruption in the two diseases. But the temperature of typhus fever is quite as characteristic as that of typhoid fever. In the latter disease we have the peculiar tidal-wave course described. In typhus fever, in the first place, the average maximum temperature is higher; for, while a temperature of 106° F. (42.1° C.) is not uncommon in typhus fever, 105° F. (40.5° C.) in typhoid is quite high. The temperature in typhus quickly reaches the maximum, usually from the third to the fifth day, continues with light remissions until the twelfth or fourteenth, then there is a sudden decline. The ascent is steady and continuous, and only marked by

slight morning remissions, while in typhoid fever the morning remissions are decided. The pulse, during the first three days, is usually about 100; after that it becomes more frequent and feeble, running up to 120 or higher, until the drop in temperature, when there is a corresponding fall in the rate of the pulse. It is seldom dicrotic, as in typhoid fever. Typhus fever more frequently begins with a *chill* than does typhoid; the important symptoms, including the eruption, appear earlier. In isolated cases, however, there may be difficulty in diagnosis.

Malignant measles, hemorrhagic smallpox, cerebrospinal fever, and bubonic plague are diseases for which typhus fever may be mistaken. The eruption of malignant measles is not unlike that of typhus fever, and it appears first in the face. The extreme adynamia and the typhoid symptoms are very similar. There is bronchitis in both, but the coryza and acute nasal catarrh are not found in typhus, while concurrent with the case of malignant measles are others of a milder and more typical nature. The latter fact also aids the diagnosis in variola, where, too, in the malignant form the hemorrhagic tendency is more marked and occurs early in the disease.

Cerebrospinal fever has often been mistaken for typhus, and in the early stage the suddenness of onset, the eruption, and the nervous symptoms are all calculated to mislead. One has to wait but a few days, however, before the courses of the two diseases diverge. *Bubonic plague* has been confounded with typhus, but it seems to have been a very different disease, resembling typhus only in its fatality. *Bubonic plague*, as described to us,—for our knowledge is from descriptions,—is characterized by the same suddenness of onset, the chill, high fever, and prostration, as is typhus fever; but the eruption appears earlier, and quickly becomes carbuncular, while the course of the disease is much shorter.

Prognosis.—The mortality of typhus is high, but different epidemics vary in this respect. During the epidemic at the Camden County Almshouse (1880-81) referred to, 103 of the officers and inmates were attacked. Of this number 23 died, giving a mortality of a little over 22 per cent. I might add that of the officers of the institution, 7, including an attending physician, the steward, the matron, the assistant matron, and 2 nurses, together with the builder of a new hospital building, were attacked, and all died. In some epidemics the mortality is even greater, reaching 50 per cent., but it is commonly put down at from 12 to 20 per cent. The disease attacks either sex at any age. One of the modes of death is by acute fatty degeneration of the heart, and the peculiar dusky complexion sometimes seen may be due to the inability of a weak fatty heart to propel the blood through the capillaries. Sudden death is not unusual. It is more than likely that with the improved nursing and hygiene of the present day the mortality of typhus would be less.

Treatment.—Whenever possible typhus fever should be treated in the open air (in tents), as the safety of attendants as well as recovery of patients is favored thereby. There is no reason why hydrotherapy should not be as serviceable in typhus as in typhoid, but it is absolutely necessary that free stimulation should be associated with any treatment. We know that the greatest danger lies in the asthenia, which can be met only by stimulants. If there is one disease in which the free use of alcohol is indicated more than in another, it is typhus fever. The quantity required, of course, must be governed by the condition of the patient. In some cases it may be necessary to give an ounce (30 c. c.) every hour. Quinin is also strongly indicated, as are digitalis and strychnin as heart strengtheners. When the temperature

becomes high, if the cold bath be not used, sponging of the body in the way described under typhoid fever may be substituted. The same objection exists to phenacetin and antifebrin as in typhoid; that is, they dare not be relied upon as an exclusive means of reducing temperature, but they may be used as adjuvants. Other symptoms should be treated as they arise. Specific anti-septic treatment has proved to be without peculiar advantage.

After the crisis, which, as has been said, is strikingly well marked in this disease, it is simply necessary to treat symptoms as they arise. The accompanying bronchitis is treated, if it requires treatment, like any other bronchitis, but the ammonium salts are especially indicated on account of their stimulating qualities, while the aromatic spirit of ammonia is an especially convenient preparation for these purposes. Alcohol, ammonia, and camphorated oil may be given hypodermically to tide over emergencies.

The patient should be nourished as in typhoid fever—by nutritious liquids, including milk, milk punches, egg-nogg, and nutritious broths.

RELAPSING FEVER.

SYNONYMS.—*Febris recurrens*; *Famine Fever*; *Seven-day Fever*; *Typhus icterodes*.

Definition.—Relapsing fever is an acute infectious disease, characterized by two or more febrile relapses separated by periods of total remission, and caused by the inoculation and multiplication of the spirochæta of Obermeier.

Historical.—Like typhus and typhoid fevers, relapsing fever is not a new malady, for a disease corresponding very closely to it was described by Hippocrates as prevailing two thousand years ago on the island of Thasus, off the coast of Thrace. Typhus and relapsing fevers often prevailed together, and many of the older reports of typhus with relapses doubtless referred to relapsing fever. Strother, in 1729, speaks of frequent relapses; also Lind, in 1763. John Ruddy, however, in 1770, gave the first clear description of relapsing fever as it prevailed in Dublin in 1739, 1741, 1745, 1748. After this many epidemics of what is evidently relapsing fever were recorded until 1817. It was still regarded as a modification of typhus, even in 1817-19, and, according to Christison, "there was a very general impression that the relapsing fever could produce the common typhus." After 1819 the disease almost disappeared until 1826, when another epidemic of both typhus and relapsing fevers broke out. Then for the first time a distinction was drawn between the two fevers, especially by Dr. O'Brien, who published an account of the epidemic as it appeared in Dublin. Numerous epidemics appeared from time to time since that date in Great Britain and Ireland and on the continent of Europe, but it has been growing less as cleanliness and hygiene improved. It prevails, also, as might be expected on account of the defective sanitary conditions, in India and Eastern Europe. It made its first appearance in America in 1844 in an emigrant ship from Liverpool to Philadelphia, and was described by Dr. Meredith Clymer. It was especially studied in India by Vandyke Carter, of Bombay. In September, 1869, it again visited Philadelphia, and New York in November, and a somewhat extensive epidemic prevailed in the former city, in which I had some experience with it.

Etiology.—That the specific cause of relapsing fever is a bacterium of the group spirobacteria, genus spirochæta, is now generally acknowledged. First discovered by Obermeier in the blood of victims, it is known by his name as the *spirochæta Obermeier*. It is a narrow spiral about 0.025 to 0.05 mm. (1-1000 to 1-500 inch) in length—that is, its length is three to six times the width of a red blood-disc. It is found floating among the blood-discs during the fever. Before the crisis and in the intervals the organism is not found, but small, glistening spherules, said to be its spores, take its place. Confirmation of the contagious nature of the disease is found in the fact that it has been communicated from one human being to another by inoculation of

blood, and to monkeys in the same way. It may be supposed that the organism is given off in the breath or from the skin. The operation of the cause is undoubtedly favored by overcrowding, by filth, and by destitution. Yet the disease is not confined to the poorly fed. This was especially proved in the Philadelphia epidemic of 1869, when a considerable number of fairly well-to-do persons were affected, although they always resided in crowded districts. Neither age, sex, nationality, nor season is a factor in its causation.

Morbid Anatomy.—There is no essential morbid anatomy, and such as is found corresponds with that of typhus. Most conspicuous is *enlargement of the spleen*.

Symptoms.—The *period of incubation* varies greatly, so that it is put down at from two to fourteen days. According to Murchison, there may actually be no interval between exposure and the invasion. The latter is sudden by a *chill, fever, intense pain* in the back and limbs, with *dizziness*. This abrupt invasion is a distinctive feature, and in perhaps none of the contagious diseases is it, as a rule, so marked. Exceptionally only is there a short period of *malaise with loss of appetite*. On invasion the temperature rises rapidly and quickly reaches 104° F. (40° C.) The patient cannot retain his feet, and promptly takes to his bed, feeling very sick, rather than profoundly weak. There may be *nausea* and *vomiting* and even *convulsions* in the young; the pulse rises rapidly, more rapidly than in typhus, reaching 140 on the second day, and later 150 and 160. The patient may be *delirious*, but the typhoid symptoms are not usually so profound as in typhus and the tongue remains moist. *Jaundice* appears in a certain number of cases on the third or fourth day, usually in one out of every 12 cases, occasionally as often as one in every four or five. The temperature during the paroxysm fluctuates slightly, being higher in the evening. *Swelling* and *sudamina* are often present, and occasionally *petechiæ*, but there is no characteristic eruption. Rarely, Murchison says in 8 out of 600 cases, a roseolar rash appears, or there may be a mottling like that of typhus, which, however, always disappears on pressure, and disappears entirely in three or four days—differing in these respects from the similar eruption of typhus. *Herpes* may be present. There is occasionally *abdominal tenderness* in the epigastric or iliac region, and the *enlarged spleen* may be easily detected, but there are no active intestinal symptoms. The *liver* may be also *slightly enlarged*, extending lower than in health.

The *spirillum* is to be found in the blood and should always be looked for. It may readily be detected with a power of 500 diameters without any special preparation of the blood, care being simply taken to secure a thin film.

Crisis.—If the invasion of relapsing fever be sudden, its termination is no less so. It is by crisis, beginning usually with sweating. After five or six days of unabated fever sweating sets in, which soon becomes profuse, the temperature falls rapidly to normal or even subnormal, the various discomforts fade away, and in the course of a few hours the patient is apparently well. Rarely, the crisis may be ushered in by a diarrhea, an epistaxis, or the appearance of menstruation.

The crisis does not always take place at the same stage of the disease. It may occur as early as the third day or not until the tenth, or even the fifteenth, but most commonly on the seventh. While the crisis is ordinarily followed by some relaxation and faintness, there soon ensues a rapid recovery of natural and healthful feeling. Occasionally, however, the depression is

Fig. 7.—Temperature Chart of Relapsing Fever, Showing Relapses.—(From Murchison on "Fever.")

greater and a sensation as of collapse occurs, especially in delicate or elderly persons.

Relapses.—Again, in a week from the crisis, generally on the fourteenth day from the primary chill, another occurs, or a series of them, with fever, and the paroxysm repeats itself, to be again succeeded by a crisis at a somewhat shorter interval. There may be a third or even fourth and fifth paroxysm; more commonly they are limited to two or at most three. Each succeeding attack is shorter than the previous one. Occasionally there is no relapse, the disease terminating with the first crisis. Convalescence, usually rapid, is sometimes prolonged, and the *duration of the entire illness* may be put down at from *eighteen to ninety days*, and the patient rarely returns to work within six weeks. One attack does not secure immunity from another.

Complications.—Among the complications may be mentioned bronchitis, pneumonia, nephritis, and hematuria. The spleen may enlarge until it ruptures. It may attain a weight of 4 1-2 pounds (10 kilos.), and may be the seat of infarcts. Albuminuria occurs as in other fevers characterized by high temperatures. Pregnant women usually abort in the relapse, and the child, if not still-born, survives but a few hours. Postfebrile paralysis may occur, and troublesome ophthalmia succeeds in some epidemics.

Diagnosis.—In its early stages relapsing fever is not unlike *typhus*. In suddenness of onset, rapid rise of temperature, habitat, and subjects, the resemblance is close. The readiness with which a patient takes his bed is characteristic of each, but in relapsing fever the adynamia is not so great as in typhus, and it is rather because of a dizziness that he cannot keep about. The crisis cuts short all doubt on this point of confusion with typhus. In the intense muscular pains, especially in the back, relapsing fever resembles *smallpox*, but the eruption in the latter disease sets doubt at rest.

Malarial fever may be suggested by the relapse, but the presence of an organism in the blood of each of these affections, widely different in appearance, permits the settlement of such confusion by the microscope. The prevalence of an epidemic is, of course, of great assistance in the diagnosis between relapsing fever and any of the diseases with which it may be confounded.

Prognosis.—The prognosis of relapsing fever is not unfavorable. The higher mortality reported in some of the earlier epidemics in Great Britain and Ireland was doubtless due to an admixture of typhus. An average for several years in a number of cities in Great Britain and Ireland, according to Murchison, has been 4.3 per cent.; in the epidemic at Bombay in 1877-78, Vandyke Carter estimated the mortality at 18.02 per cent.; while in the Philadelphia epidemic the studies of William Pepper and Edward Rhoads found it 14 per cent. I am sure that in private practice during this epidemic the mortality was not so great. There are some accidents, which have been already alluded to, that are responsible for a few deaths. Thus, the spleen has ruptured from extreme congestion. Pneumonia sometimes causes a fatal termination. It has been said that the crisis sometimes terminates in collapse with its characteristic clammy coldness, pulselessness, unconsciousness, and fatal end. A fatal nephritis occasionally complicates the disease, death being preceded by uræmic convulsions. Certain cases associated with jaundice, called by Griesinger "bilious typhoid," are often fatal. Some striking cases of this kind were noted by Pepper at the Philadelphia Hospital in the epidemic of 1869-70.

Treatment.—The febrile paroxysm demands much the same treatment as in typhus—careful nursing, sponging or cool bathing, nutritious, easily

assimilable food, and stimulation, although the latter is less important than in typhus. No drug has the power to prevent the recurrence of the relapse, although quinin is indicated, and, as in other adynamic fevers, is useful as a roborant. It is reasonable to expect that phenacetin, antifebrin, or antipyrin will relieve the muscular pains. Should they not suffice, morphin, hypodermically, can be relied upon.

MALTA FEVER.

SYNONYMS.—*Mediterranean Fever*; *Neapolitan Fever*; *Rock Fever*; *Undulant Fever*.

Definition.—An anomalous fever, characterized by irregular remissions and relapses, copious sweats, and rheumatoid pains, caused by the *micrococcus melitensis*.

Distribution.—The various names of Malta fever indicate its distribution on the Mediterranean littoral, outside of which it has been thought infrequent; but in 1898 J. J. Kinyoun* suggested its presence on the Southern Atlantic coast of America and the islands of the Gulf of Mexico, a suggestion confirmed by the report by J. H. Musser and Joseph Sailer of a case originating in Cuba.†

Etiology.—The cause of this peculiar fever, the *micrococcus melitensis*, has been studied by Bruce, whose researches have been confirmed by Hughes. Its morphological and biological features have been accurately studied by H. E. Durham. It is found in large numbers in the spleen, but has not been isolated from the blood. Pure cultures have been obtained, the disease has been reproduced in monkeys, and the micrococcus isolated from the infected animal. It has been regarded as a form of typhoid, malarial typhoid, and in consequence of enlargement of the mesenteric glands, noted by Italian observers, called adenotyphoid. It has also been thought to be an anomalous form of malarial fever, and ascribed to "chronic poisoning with fecal accumulation." On the other hand, it does not give the Widal typhoid fever reaction, while A. E. Wright and F. Smith have shown that the blood of Malta fever patient reacts with pure cultures of the *micrococcus melitensis*. This would seem to settle its independent nature. The disease attacks mostly the young.

Morbid Anatomy.—Our knowledge of the morbid anatomy of Malta fever is not definite. Thus, Bruce says no characteristic lesion of typhoid fever is found, while Perry says of "rock fever" that in 100 autopsies made during four years' residence in Gibraltar, the typical lesions of typhoid were present without exception. Hughes also says the spleen is enlarged.

Symptoms.—There is usually a *period of incubation* of from six to ten days. The onset is gradual, with *headache*, *sleeplessness*, and *thirst*, *loss of appetite*, *without chilliness* or *high fever* at first. There is no diarrhea; spots are not found. These symptoms, more or less pronounced, last from three to four weeks, when the first remission sets in, simulating convalescence. It lasts a few days only, when the first relapse appears, this time with *rigors*, *high fever*, and often *diarrhea*, and the symptoms of the first attack intensified. This relapse lasts for from five to six weeks, to be followed by another remission of from ten days to two weeks. Then follows the second relapse, when recur the symptoms of the first relapse, to which

CHART OF MALTA FEVER SHOWING MORNING AND EVENING TEMPERATURES.

TWO DISTINCT RELAPSES ARE SHOWN.

Fig. 8.—(After Musser and Sailer.)

are superadded great *debility*, *night-sweats*, *pain* in the larger joints, including hips, knees, and ankles, and in the testicles—one or both—lasting three or four weeks. Then follows a third remission, which may last for a month or six weeks. Then a third relapse of shorter duration, adding to the other symptoms a heavily *coated tongue*, a high temperature, 105° F. (40.5° C.) and above in the evening, but normal in the morning, the night-sweats, and especially the rheumatic pains, being markedly severe. All the joints now seem to be involved, and motion is an agony. The fibrous tissues are also often involved in this relapse, especially the *tendo Achillis* and fibrous structures about the ankle; also the lumbar aponeuroses and sheaths of the nerves from the sacral plexus.

Diagnosis.—The rarity of the disease and the peculiarity of its symptoms may cause it to be overlooked for some time. The serum reaction is, however, characteristic, cultures of the specific bacillus responding to the serum of the blood of the disease as in typhoid fever.

Prognosis.—This is generally favorable, not more than two per cent. perishing.

Treatment.—This is symptomatic, being directed to the relief of the symptoms and the support of the patient against the exhaustive effects of the disease. A case seems to have been successfully treated with Malta fever antitoxin by Fitzgerald and Ewart.*

THE MALARIAL FEVERS.

SYNONYMS.—*Ague*; *Fever and Ague*; *Chills and Fever*; *Marsh Fever*; *Swamp Fever*; *Paludal Fever*; *Miasmatic Fever*; *Intermittent*, *Remittent*, and *Pernicious Remittent Fever*; *Bilious Fever*; *Estivo-autumnal Fever*.

Definition.—An infectious fever, of intermittent or remittent type, due to an organism known as the *plasmodium* or *hematozoon* of malaria.

A chronic cachectic condition due to the same cause is known as “chronic malaria” or “malarial cachexia.” Chronic malaria has really a more definite morbid anatomy than the acute malarial fevers. The term “malaria”—meaning, in the Italian, bad air—was originally applied to the supposed specific cause of the fever, but it is also used to express the consequences of such cause.

Varieties of Malarial Fever.—The malarial fevers are *intermittent* or *remittent*. The former is characterized by paroxysms of fever, between which there are total intermissions. In the remittent form there are remissions or abatements in the fever, but not intermissions. The remittent fevers exhibit much less regularity than the intermittent fevers, even in their remissions, and in consequence of their prevalence in the later summer and fall have recently among other irregular types been included under the head *estivo-autumnal*. This term embraces also all the malignant types, which are rarely seen in the spring months. The term “irregular” malarial fevers is quite as distinctive and perhaps more accurate.

The paroxysms of fever may come on daily at the same hour, when they are called *quotidian*; they may occur every other day, when they are known as *tertian*; or they may occur every third day,—that is, skip two days,—when they are called *quartan*. More rarely occur *quintan*, *sextan*,

* “The Lancet,” April 15, 1899.

septan, and octan fevers, with intervals of four, five, six, and seven days, respectively. It will be noted that in naming these periods the day of the paroxysm and that of the following paroxysm are both counted. The "double tertian" is a fever in which paroxysms occur each day but at different hours, the hours on alternate days corresponding with each other. In these cases the alternate paroxysms may also be of different intensities. In like manner there may be double quartans and even double quotidians.

Although the paroxysms in true intermittent fever commonly occur at the same hour, they may happen a little earlier each day, when they are called "retarding." The former is apt to occur when the disease is becoming more severe, the latter when it is abating. The paroxysm varies in length in the different varieties. In the quotidian form it lasts from ten to twelve hours, in the tertian six to eight hours, and in the quartan four to six hours.

Malarial cachexia referred to in the definition, also known as chronic malaria, will be fully considered later.

Etiology.—The malarial fevers are to-day believed to be caused by a protozoön known as the *plasmodium malariae hematazoön*, or *hematomonas malariae*. These fevers have ever been a field which seemed to promise reward to the seekers after such a cause. In the days of Hippocrates (B. C. 460-357) it was recognized that marshes breed malaria. John K. Mitchell,* an eminent American physician, was, however, the first to suggest, in a scientific manner, the parasitic origin of malarial fever. This was in 1849; in 1859 John K. Barnes,† of the United States Army, also called attention to such a mode of origin. In 1869 Binz, the pharmacologist, declared that the cause of malaria was an ameboid protozoön, because of the specific action of quinin on ameboid organisms. Massy, Basa, Wiener, Polk, Holden, Salisbury, and others, all suggested a fungous origin of malaria on more or less unstable foundations. It was not until 1879 that Ed. Klebs and C. Tommasi-Crudeli succeeded in isolating a germ which they called *bacillus malariae*, from the low-lying atmosphere over marshes and from the soil itself, the inoculation of which into rabbits, they alleged, produced malarial paroxysms with enlargement of the spleen and pigmentation. No permanent impression was, however, made by this announcement. The very next year, 1880, A. Laveran, a French army surgeon, discovered the plasmodium referred to, and announced the discovery to the Paris Academy of Medicine in 1881 and 1882. His researches were made in Algiers, and in the course of the next three years he published numerous papers. His results were confirmed by Richard in 1882. E. Marchiafava and A. Celli published, in 1885, their observations on the same organism in the blood of malarial patients in Rome. These observers were the first to insist upon the ameboid property of the intracellular form. From this time our knowledge has been enormously extended by many observers, among whom may be especially mentioned Golgi (1885-92) and Canalis (1893) in Italy; Vandyke Carter (1887) and Patrick Manson (1893-96) in England; in this country A. C. Abbott, W. T. Councilman (1885), Surgeon General Sternberg and William Osler (1886), Walter James (1888), George Dock (1889-92), William Sydney Thayer and John Hewetson as authors of a masterly monograph in 1895, and James Ewing in 1900; Patrick Manson (1894-96), Surgeon Major Ronald Ross (1895-96), and Daniels (1899) in England from their India studies; Grassi, Bignami, and Bastianelli (1898-

* "On the Cryptogamic Origin of Malarias and Epidemic Fevers," "American Journal of the Medical Sciences," Philadelphia, 1849.

† "U. S. Army Reports," 1859, p. 163.

99) in Italy, and W. G. MacCallum and Eugene L. Opie in this country, have developed the mosquito theory to a positive demonstration that malaria may be conveyed from the mosquito to man, and from man to the mosquito.

To Study the Malarial Organism.—The malarial organism* is best studied as follows:

A drop of blood is taken from the finger or lobe of the ear of a case of ordinary tertian intermittent fever during the chill, or an hour or two previous, while the temperature is gradually rising. It should be suitably spread on a slide and carefully examined by the microscope. There will probably be found a number of pale, mulberry-like bodies analogous to those in figure 9, A_2 , A_3 , made up of from twelve to twenty segments, massed about a clump of black pigment granules. Careful focusing will show that this body lies within a red blood-corpuscle, whose delicate walls and pale substance surround it. If, now, a little solution of gentian-violet or fuchsin be successfully added to the preparation, the stain will impart itself to each of the little segments, differentiating a deep-tinted central nucleolus and more lightly stained surrounding protoplasm. In the same slide may be seen other similar bodies (B_1 , B_2), inclosed in the ring of hemoglobin, loosely arranged, apparently falling apart; also small, pale spherules (C_1 , C_2) floating alone in the liquor sanguinis, apparently derived from the same source.

If the blood be taken during the chill, careful searching may also discover certain red corpuscles (D_1 , D_2) on which are imposed minute pale spots (epicorpuscular) which exhibit ameboid movement. These also take a stain which may develop a central nucleolus and lighter surrounding area, deepening in color at its periphery. The colorless intermediate area is usually interpreted as a bladder-like nucleus, the deeper-stained dot at one side representing the nucleolus which is not apparent in the unstained specimen. Sometimes there is more than one disc-like body. A few hours later, after the chill, none of the free bodies described is visible, but within

* These organisms are readily seen with a power of 500 to 600 diameters, but are best studied when magnified 1000 times, say by an oil immersion $\frac{1}{12}$ th. For more precise study take from the finger-end, or better, the lobe of the ear, thoroughly cleansed, a drop of blood and place on a sterilized cover-glass, which should then be allowed to fall gently on a glass slide, without pressure. If the study is prolonged, the edge may be sealed with paraffin, or a ring of oil. Staining may be practiced as follows:

A thin layer of blood is spread on several clean cover slips, which are first left to dry in the air for a few minutes, and then placed in absolute alcohol to fix the blood corpuscles and parasites. After 13 to 20 minutes the cover-slips are dried and are ready for staining, although the last stage may be deferred indefinitely.

They may be stained with saturated solution of methylene blue, which, as shown by Celli and Guarnieri, is best dissolved in blood serum or ascitic fluid.

Double staining, which, if successfully performed, gives brilliant results, should be done by Ehrlich's method, as modified and improved by Romanowsky, 1890; Ziemann in 1893, and Nocht in 1899. The staining fluid is a mixture of a one per cent. solution of eosin with a saturated solution of methylene blue, which develops a third stain that colors the chromatin. The eosin stains the red discs pink, the methylene blue stains the hemosporidea blue, while the third stain colors the chromatin a violet tint.

To prepare the Nocht-Romanowsky staining fluid, Ewing directs as follows. Make first the following three solutions:

(1) *Polychrome Methylene Blue Solution.*—To 1 oz. of polychrome methylene blue (Grübler) add 5 drops of 3 per cent. solution of acetic acid (U. S. P. 33 per cent.) to neutralize the undue alkalinity.

(2) *Ordinary Methylene Blue Solution.*—Make a 1 per cent. (saturated) watery solution of methylene blue, preferably Ehrlich's rectified, or Koch's, by aid of gentle heat. This solution improves with age and should be at least a week old.

(3) *Eosin Solution.*—A 1 per cent. solution in water of Grübler's aqueous eosin.

Then to 10 c. c of water add 4 drops of (3), 6 drops of (1), and 2 drops of (2), mixing well.

To Use.—The specimens fixed by alcohol or heat are immersed for two hours specimen-side down, and will not overstrain by twenty-four hours' immersion. They should be then washed in distilled water, dried slowly over the flame and mounted, if desired, in Canada balsam. The density of the blue may be varied to suit individual fancy, nor need the proportions be rigidly followed, but most important is the accurate neutralization of the polychrome solution.

Preliminary studies may be made of the *drepanidium ranarum*, a similar parasite in the red corpuscle of the frog (Osler. "Canadian Lanæet." No. 7, 1882); or on the hematozoa of birds. (See papers by W. G. MacCallum and Eugene L. Opie in "Jour. of Experimental Medicine," vol. iii. No. 1, 1898; see also Angelo Celli's admirable book on "Malaria," 2d ed., translated by John Joseph Eyre, London, 1900, where the whole subject is treated most interestingly and fully.)

Drawings in the upper part of the plate from the blood of a case in the wards of the Hospital of the University of Pennsylvania, those in the lower portion selected.

the corpuscles are seen actively moving ameboid bodies (E_3 , E_4) of considerable size, constantly changing shape, and sending out pseudopodia into the substance of the blood-corpuscle. These intracorpuseular bodies stain with the same differentiation as the smaller disc-like bodies, but the nucleus is larger and less distinct. Many of them contain one or more dark granules in active motion.

Still later, toward the next paroxysm, the pale body fills the entire corpuscle, its ameboid movement ceases, while the pigment granules are more numerous and stationary. It has, moreover, lost its nucleus and nucleolus. The pigment now tends to mass itself into clumps or radiating lines, and just before, or at the time of the chill, the picture first described, of rosettes or loosely attached and free spherules, is seen. The same cycle of successive steps is kept up from paroxysm to paroxysm. The conclusion reached by all observers is that the large intracorpuseular body (Fig. 9, A_1) is the mature parasite ready for sporulation, and the mulberry mass presents the sporules perfectly formed, which a few seconds later become free spherical spores. These attach themselves to the red discs, penetrate them, and grow at the expense of the hemoglobin, leaving the black granular residue as excrementitious substance, which is let loose in the blood at the time of sporulation. As a consequence of this, the presence of pigment in the blood and tissues is one of the most characteristic features of malaria.

The time required to attain the perfect growth, from the free sporule to the last stage of sporulation, varies in the different varieties of malarial fever. During this period certain groups, perhaps numbering myriads of corpuscles, pass through the same stages, and the final sporulation of such a group of parasites is always followed by the malarial paroxysm. This is probably due to some toxic substance developed at the time of sporulation. Thus, with the typical quotidian type, sporulation takes place every day at the same hour, with the tertian type every other day, the quartan type every seventy-two hours, and so on. If, however, two groups ripen at different hours, we have the double forms, be it double tertian or double quartan. Or two groups of tertian parasites may mature on alternate days, causing a quotidian paroxysm, though at different hours. A paroxysm may be expected at once in the tertian form, if radiating lines appear in the organism with concentration of pigment. The cycle of existence of the estivo-autumnal type has an undetermined duration, and probably varies from twenty-four to forty-eight hours. The irregular ripening of different groups would explain the irregularity of the estivo-autumnal forms of fever, which may begin as regular types.

Attempts are further made to differentiate the parasite of the different types of fever by its dimensions, rapidity of ameboid movement, size and number of pigment granules, number of segments in sporulation, etc. Thus the full-grown *parasite of tertian fever* is about as large as a normal red blood-corpuscle, beginning its cycle of development as a much smaller hyaline ameboid body. It acquires rapidly fine, brown pigment granules formed at the expense of the surrounding blood-disc, which, becoming gradually decolorized, becomes larger and more indistinct until it disappears. The granules exhibit active movement. In the sporule stage the segments number from fifteen to twenty, or even more. The parasite has a cycle of 48 hours.

The *parasite of quartan fever* is very similar, but it is smaller; its ameboid movements are slower, and the pigment granules coarser, darker,

and less active in motion. The red corpuscle embracing it, instead of becoming larger and paler, shrinks about the parasite and assumes a deeper, greenish hue. The sporulation segments are fewer, only from five to ten in number, and arranged with great regularity about the central pigment (Fig. 9, A_2). Its cycle is 72 hours.

The *parasite of the estivo-autumnal fever* is still smaller, being, when fully developed, often less than half the size of a red blood-corpuscle, and the quantity of pigment is much smaller. Only the early stages of its development, represented by small hyaline bodies, often with one or two pigment granules, are found in the peripheral circulation, the later stage being seen in the blood of internal organs, such as the spleen and bone-marrow. The fewness of the pigment granules is characteristic. The corpuscles containing the parasite are also apt to become shrunken, crenated, and brassy in color. After a week or more, the larger crescentic ovoid and round bodies to be described make their appearance, and are characteristic of this form of fever. The cycle of this parasite is about 48 hours.

The large *extracorpuseular* body (F_1, F_2), which presents the same pigmentation and other features of the intracorpuseular body, is the latter escaped from the corpuscle. The event of its escape may sometimes be observed while studying blood taken about the time when most of the intracorpuseular bodies have disappeared by sporulation. Such escape, it is thought, does not take place in the living blood, since the corpuscle is not found in preparations, dried or "fixed," *immediately after the removal* of the blood from the body. It is found, however, in preparations watched with the microscope for some minutes after being taken.

The *crescent-shaped* parasite (Fig. 9, $H_1, H_2, H_3, H_4, H_5, H_6$) is also a striking object, far less frequently met, at least in the vicinity of Philadelphia, than the ordinary pigmented form. Unlike the large extracorpuseular form already described and the flagellate form to be next described, it is apparently a constituent of living blood, and, according to the studies of Thayer and Hewetson, as well as the earlier ones of Marchiafava and Celli, appears in most of the cases of estivo-autumnal fever after a certain time, generally during the second or third week, and not in the cycle of development of tertian or quartan fevers. The crescent develops in the interior of the red corpuscle from the small hyaline forms, which gradually increase in size, lose their ameboid movement, and assume a crescentic shape, while pigment granules collect in a group at the center. The corpuscle itself gradually becomes decolorized and ultimately destroyed, though for some time a delicate line can be seen running between the horns of the crescent, a shell, as it were, of the corpuscle in which the parasite is developed. The crescents in turn change into elliptical, ovoid, and finally round forms. When the round form is assumed the pigment starts into active motion, and sporulation may take place. Such sporulation may also, according to Canalis, Manson, and Ross, be by flagellation.

The *flagellate organism* (G_1, G_2) may also come into view on the slide some fifteen or twenty minutes after the blood is mounted, but is never seen on slides "fixed" immediately after the blood is drawn. It develops from the full-grown tertian and quartan parasites and from the round bodies with central pigment in estivo-autumnal infections. It is a very interesting object, the tentacle-like prolongations lashing about the central mass and agitating the surrounding corpuscles in a seemingly violent manner, throwing the latter and its own melanin particles into a state of extreme commo-

tion. Sometimes portions of these tentacles break loose and float away in the blood plasma.

It will be noted that no quotidian parasite is described. It is not thought that a special form causing this variety of intermittent fever exists, but that the quotidian paroxysm is due to the maturation on successive days of two swarms of the tertian parasite.

Though the mosquito theory of malaria is by no means new, it was not until 1894 that Patrick Manson gave it definiteness by suggesting the mosquito might be the intermediate host for the extracorporeal forms of the parasite, that the flagellate form is the first extracorporeal stage, and that the flagella, breaking off from the residual body, may penetrate the cells of some organ of the insect. He first claimed that the crescentic form of estivo-autumnal malaria and the tertian and quartan spherical forms from which develop flagella are the "extracorporeal sporulating homologues of the intracorporeal organism; that the flagellum is the extracorporeal homologue of the intracorporeal spore." Both types of sporulating plasmodium possess the same function,—the propagation of the parasite,—one in the human body; the other, outside of it. Surgeon Major Ronald Ross, whose studies were stimulated by Manson, found the flagellate form in the stomach of mosquitos that had fed on subjects suffering with estivo-autumnal fever whose blood contained large numbers of crescents, confirming Manson's observations. Again, Daniels, working in Calcutta under Ross' direction, was able to confirm all the latter's observations. Angelo Celli, while admitting that Ross partly saw the first stages of development of the estivo-autumnal parasites in the body of a dapple-winged mosquito, holds that Grassi, Bastianelli, and Bignami have given us all the details of its development.* W. G. MacCallum demonstrated in his observations on *halteridium of Labbé*, a malarial parasite of birds, that the flagella represent male sexual elements.

Favoring Causes and Geographical Distribution of the Malarial Fevers.

—Such is the belief as to the immediate cause of malarial fever at the present day, evidence being strongly in favor of the view that inoculation is the only mode by which the infection is carried from the mosquito to man and from man back to the mosquito. Indeed, most recent studies by the Italians, Bastianelli and Bignami, have determined the species of mosquitos that are capable of producing two forms of infection. They are the *anopheles claviger* and *anopheles pictus* (dapple-winged mosquito of Ross), both conveying the estivo-autumnal form, while the former is the conveyer of tertian infection. These views are further confirmed by the conditions which favor malarial fever, and these conditions, notwithstanding exceptions, are hot climates and hot seasons plus decomposing vegetable matter, low river banks frequently covered and uncovered with water and exposed to the sun—in a word, conditions that favor the breeding of mosquitos.

Wherever these conditions occur, malaria is rife. Especially are they found in the southern borders of the north temperate zone, as in Southern United States, Southern Italy, and along the lower Danube; the northern border of the south temperate zone, in the tropics, as Central America, the West Indies, Central Africa, and Southern Asia. A freshly upturned soil may furnish, under a sufficiently high temperature, a minimum of 60° F. (15.6° C.), as favorable a focus almost as a marshy river bank. All ages are susceptible, but children are especially liable to take the

* Celli, "Malaria," 2d ed. Translated by John Joseph Eyre, London, 1900.

disease on exposure. More men have it than women, for evident reason. Currents of air carry the disease to localities in which it is not primarily engendered, only by carrying the mosquitos laden with the extracorporeal forms. Water ingested cannot be a cause of malarial infection, according to modern views.

Morbid Anatomy.—The morbid anatomy of malaria includes mainly changes in the blood, the liver, and the spleen,—changes that vary with the duration and intensity of the disease, to which, however, they do not always correspond.

As to *acute malaria*: In the true *intermittent* fevers there is a loss, sometimes considerable, of red corpuscles after each paroxysm, which is made up during the intermission. In the *estivo-autumnal* form the blood losses are greater and more permanent. The absence of leukocytosis is characteristic. In *remittent* and *pernicious* malaria—the latter a form characterized by the intensity of the poison and severity of the symptoms—the morbid changes may not be very striking if the patient die in the first attack, but more marked after a second. The blood is described as hydremic, the serum is sometimes tinged with hemoglobin, and the corpuscles, while containing the parasite, present all stages of destruction. The spleen is enlarged, but not nearly so much as in chronic recurring forms of malaria. It is, moreover, soft and its pulp is dark from accumulated pigment in the intervacular cords. The *liver* is enlarged and dark-hued, sometimes described as bronze and sometimes slate-color. Even when not visibly altered to the naked eye, there may be no difficulty in recognizing the excess of pigment within and without the small vessels, some of which may be occluded. In fact, by the aid of a microscope, almost all the tissues may be found abnormally pigmented, even the brain, some small vessels of which may also be occluded. The *kidneys* are the seat of pigment deposits, and their cells of cloudy swelling.

In *chronic malaria* the *blood changes* are even more marked. There is a positive secondary anemia in which, as usual, the hemoglobin is decreased rather more than the corpuscles. The leukocytes are almost invariably diminished, the polynuclear leukocytes most, while the larger mononuclear forms are relatively increased. Pigment deposits are abundant, especially in the spleen, which is enlarged and hard.

In chronic malaria, of whatever form, the *enlarged spleen* is the most characteristic morbid product. It may weigh as much as ten pounds (4.5 kilos.) and measure ten inches (25 cm.) long and four (10 cm.) to six (15 cm.) in width; its capsule is thickened, its substance firm, and the trabeculæ prominent. Pigmented areas abound, due to the plugging with pigment of the intercommunicating lymphoid spaces of the pulp, and in some cases the melanosis is general. The pigment particles resulting from the disintegration of the hemoglobin in the vessels are retained in the spleen, as by a filter.

The *liver* is also enlarged, to a less degree, however, than the spleen. It is indurated and presents various degrees of pigmentation, which may reach a slate-gray tint. The pigment is contained in the portal canals and beneath the capsule.

The *kidneys* may be similarly pigmented, the pigment lying about the smaller blood-vessels and the Malpighian bodies, and in the cells lining the tubules. In protracted cases of malarial cachexia other tissues may be pigmented. Thus, the small vessels of the brain may be surrounded by

pigment and even occluded, so that hemorrhagic infarcts may occur. Even the mucous membrane of the stomach and the peritoneum may be pigmented in extremely chronic cases. Malarial poisoning is included among the causes of chronic nephritis, but, in considerable experience with renal diseases, I can recall but one or two cases of nephritis doubtfully traceable to this cause.

CLINICAL VARIETIES.

The chief varieties of malarial fever admit of easy separation by their symptoms.

INTERMITTENT FEVER.

Definition.—This form of malarial fever is characterized by a total remission of fever between paroxysms.

Symptoms.—This, the well-known fever and ague, characterized by distinct paroxysms of chill, fever, and sweat, has a distinct *period of incubation*, which may be as short as twenty-four hours or even less, though usually it is from a week to fourteen days. Sometimes it is very much longer, and even months are said to elapse after exposure before the first paroxysm sets in. The paroxysm is usually preceded by a prodrome of uneasiness and discomfort, sometimes languor and yawning, sometimes headache, sometimes nausea, which forewarns the patient of its coming. As often as not there is no such prodrome. The paroxysm consists of the chill or cold stage, the fever, and the sweat.

The *chill* commonly begins gradually. First there is a creep, then another a little more severe, then another, each growing in severity until the teeth chatter and the body shakes violently. There is, however, great difference in the severity of the chill. It may be a barely noticeable creep or such a chill as will cause the bed and even the windows of the room to shake. At the same time the patient's lips are blue, his face is pale and pinched, and he looks very cold. Yet he has fever. Even before the chill there is a slight rise in temperature, and during it the latter may reach 105° F. (40.5 C.) and 106° F. (41.1° C.) in the axilla or mouth. A surface thermometer may show a lower temperature of the skin, but the internal heat is in strong contrast with the apparent coldness. There may be nausea or vomiting and severe headache. The pulse is small, hard, and frequent. The hands are pale, cold, and the nails blue. The urine is increased, light-hued, of low specific gravity, though before the chill it may be concentrated and the specific gravity high. The duration of the chill varies from a *few minutes to an hour or more*.

To the chill succeeds the *fever*. The skin is intensely hot and dry and the face flushed. There is intense thirst. The mouth is dry, the tongue coated, the breath foul. There is no mistaking this stage any more than the first. Yet the actual temperature is but little higher than during the chill. This is well shown in the appended chart, in which it will be seen that the temperature during the chill at two successive observations was 104.2° F. (40°C.) and 104.4° F. (40.18° C.); during the succeeding *fever* it reached at the first observation 104.8° F. (40.4° C.), and at the second, 105° F. (40.45° C.). The duration of this stage is from *half an hour to four or six hours*.

The *sweating stage* follows, with the appearance of drops of sweat on

the face, whence it extends all over the body and is various in quantity. With it comes relief to all the symptoms. Indeed, a sense of great comfort supervenes. It may be a mere suggestion of moisture, or it may be very profuse, drenching the patient's clothing and even wetting the bed. It is commonly proportionate to the severity of the chill. During the sweat the temperature falls rapidly, but if the paroxysm is severe several hours elapse before it attains the normal. It lasts for *half an hour to two hours*, after which the patient feels comfortable and well.

It is not easy to give a satisfactory *rationale* of the three stages. The

Fig. 10.—Temperature Chart in Intermittent Fever, Showing Paroxysms and Intermissions.

It will be noted that the temperature has been taken during the chill, and during the fever just after the chill, and that although, as is well known the fever is very high during the chill while the patient *feels* cold, it is still a little higher during the fever just after the chill.

first and second are undoubtedly the direct result of the same cause—a toxin generated by the plasmodium, since the actual fever which characterizes both is irritative. The superficial coldness and sense of cold of the first stage may be the result of vasomotor spasm contracting the blood-vessels of the surface and due to an irritation of vasomotor centers by the toxin; the second stage to a derangement of the heat-regulating centers. The third stage is probably a reactive vasomotor paralysis, with the usual leakage from the skin incident to it.

The total duration of the paroxysm is from *eight to twelve hours*, and usually between the paroxysms the patient feels perfectly well. During the paroxysm the *spleen* becomes *enlarged* and the malarial patient has often *herpes labialis*, a symptom which is almost pathognomonic of malarial fever. The size of the spleen subsides after the paroxysm, although with its repetition there is a disposition to permanent enlargement, resulting finally in the ague cake.

The types of the paroxysm so characteristic of intermittent fever have already been referred to. The order of frequency is quotidian, tertian, and quartan; the first being by far the most frequent.

Diagnosis.—The diagnosis of intermittent fever is most easy, and a typical case should be easily recognized after the second paroxysm, if not after the first. If the case be less typical and the chill omitted or so slight as to escape recognition, a certain resemblance between such a paroxysm and the *hectic fever of tubercular consumption*, with its subsequent sweat, must be admitted, and it not infrequently happens that such fevers are

Fig 11.—Temperature Chart in Intermittent Fever, Showing the Paroxysms and Intermissions.

declared to be malarial by the attending physician—more frequently, it is to be hoped, for the sake of comforting the patient than as a matter of accurate diagnosis.

Still more close is the resemblance of the paroxysm to the chills, fever, and sweats of *septicemia* and *pyemia*, while suppuration is frequently ushered in, and its progress associated with like symptoms. Other conditions calculated to produce these symptoms may generally be discovered on careful inquiry, though they may escape notice for a time. In addition to suppuration, surgical operations, catheterization, puerperal fever, the incidence of empyema, and the like, all produce chill, fever, and sweat. The so-called

nervous chill is easily distinguished, because with it there is no rise of temperature—at least nothing at all comparable to that of the malarial chill. The possible combination of malaria with other causes of chill and sweats is to be remembered. A search for the hematozoön, scarcely necessary for diagnosis in typical cases, may under such circumstances prove extremely useful.

Prognosis.—The prognosis of simple intermittent fever is always favorable. Very frequently, if the disease is not treated by medicine, it will exhaust itself in a couple of weeks and disappear, while the administration of suitable doses of quinin always puts an end to it. The worst that can happen is the conversion of the disease into chronic malaria or the malarial cachexia. This may occur when treatment is neglected, or when constant exposure to the cause operates to produce such a state notwithstanding suitable treatment.

REMITTENT FEVER—ESTIVO-AUTUMNAL FEVER.

Definition.—Remittent fever is the form of malarial fever characterized by a continued fever with paroxysmal exacerbations. It is also known as bilious fever. It has become rare at the present day in the North Atlantic States of America, and is confined mainly to the South, to Italy, the lower Danube sections in Europe, and to tropical countries. It occurs in the late summer and fall, and hence is included among the *estivo-autumnal* fevers.

Symptoms.—It generally begins with a *chill* after a *period of incubation* analogous to that of intermittent fever. It is more likely to be preceded by *prodromal symptoms* than is intermittent. There are malaise, intense headache, a coated tongue, and often obstinate nausea and vomiting. Vomiting of bilious matter is a conspicuous symptom. These gastric symptoms, formerly ascribed to gastritis, are probably caused by central nervous irritation due to the toxin. There may be *jaundice* resulting from obstructing cholangitis; the liver may be tender on pressure. The chill may be less severe, and the other stages of the paroxysm less characteristic. The fever does not pass off, but continues with a full, bounding pulse and a temperature of 102° to 103° F. (38.9° to 39.5° C.). There are daily remissions, as in typhoid fever, but they do not follow the same rule of tidal rise. Yet the two diseases are very similar, and often thoroughly try the diagnostic skill, even of those who are accustomed to meet bilious remittent fever. The temperature rises quite as high as in typhoid fever, and the patient is usually very ill. The two diseases occur at the same time of the year—the autumn. It is not impossible for them to be concurrent.

There is little else that is peculiar in the symptomatology of the common forms of remittent fever besides the prodrome, the malarial organism, and the peculiar paroxysmal character. In prolonged remittent fever the typhoid state is sometimes assumed, manifested by dry tongue, hebetude, stupor, and feeble, frequent pulse.

The *urine* is high-colored, with high specific gravity, depositing a copious sediment of urates, and sometimes contains biliary coloring-matter. Not infrequently it contains blood-corpuscles or hemoglobin.

Diagnosis.—As intimated, it is with typhoid fever that remittent fever is most likely to be confounded. Occasionally in the South there has been confusion with yellow fever. To us who study *typhoid fever* in the North it seems surprising that there should be any confusion with this disease. It is ordinarily so easy, after watching the temperature chart for a few days, to

recognize typhoid fever. In the South it is, however, different, and, before the discovery of Laveran's plasmodium, the therapeutic test—administration of quinin—was frequently needed to settle the question; for remittent fever, like intermittent fever, yields to quinin. In such cases a successful search for the hematozoön will settle the question promptly. This is the variety in which we have the small, actively motile hyaline forms of organism, while the larger crescentic, ovoid bodies are to be looked for as soon as the disease has existed over a week. An unsuccessful search may still leave the matter in doubt, but if the nasal hemorrhage, the typhoid spots, the diarrhea of typhoid, and the temperature are not sufficiently characteristic, the quinin test ought to put an end to all doubt. The Widal test has come to our aid, also, of late, and if responded to affords conclusive evidence of the presence of typhoid fever. Although it may seem presumptuous for one who has not practiced in the South to say it, such study as I have been able to give to the subject impels me to say, with Osler, that all of the continued endemic fevers of the South may be resolved into typhoid or malarial fever.

The diagnostic distinction between remittent fever and *yellow fever* will be given when considering the latter disease.

Prognosis.—This is usually favorable when treatment can be promptly applied.

PERNICIOUS MALARIAL FEVER—THE CONGESTIVE CHILL.

Definition.—This variety of malarial fever is characterized by the extreme severity of its paroxysms.

Occurrence.—It still presents itself occasionally in the North, but is much rarer than it was fifty years ago. Up to a few years ago it was not uncommon to hear of the death from this cause of a prominent citizen at his country seat on the banks of the Delaware above Philadelphia. Later, the cases became confined to the servants and others out late at night or early in the morning, and, more recently still, even such cases as these are seldom reported, although the milder forms of malaria prevail. It is still prevalent in the Southern United States, in Italy, the lower Danube, the Niger delta, and other parts of tropical Africa. According to the Italian observers, pernicious malarial fever is associated with the small plasmodium.

Two principal types present themselves—the *comatose* and the *algid*. Other forms, named from special features more or less characteristic, are the *hematuric*, the *bilious* and the *asthmatic* types. As malarial hematuria is not confined to the pernicious variety, it will receive separate consideration. The bilious type is that of the ordinary severe form of remittent fever, while asthma characterizes the comatose and algid types.

1. The *comatose* type may or may not begin with a chill, but in its more serious forms the chill is a conspicuous feature, being severe. To it succeeds the comatose state, whence the term *congestive chill* often used in the South, where the popular notion prevails that if the first paroxysm does not kill, the second will. This is an exaggerated idea of its seriousness, although it is certainly a very grave affection and often terminates fatally. A low, muttering delirium may supervene, the eyes are bloodshot, the skin is hot and dry, the temperature rising to 105° or 106° F. (40.6° or 41.1° C.). The comatose condition is probably a toxic one, and lasts until a partial elimination of the poison has taken place, usually from twelve to twenty-four hours later. The patient may, however, perish without return to conscious-

ness, or consciousness may return to be followed in a short time by fatal relapse.

2. The *algid* type is characterized by gastric symptoms, extreme nausea and vomiting, which are mostly followed by collapse, for there is intense prostration, with coldness of the surface and extremities. The symptoms are, indeed, comparable to those of the collapse of cholera. There are the same small, feeble pulse, frequent, shallow breathing, cramps, vomiting, purging, husky voice, and thirst with suppressed urine, and with these the same clearness of intellect until death steps in—the last scene in the drama, in which asthenia also plays a leading rôle.

In these cases there may or may not be a chill, yet the patient feels cold and the surface temperature is never high, rarely exceeding 101° F. (38.3° C.), and falling as low as 96° F. (35.6° C.). The internal temperature is, however, high.

Diagnosis.—Pernicious malarial fever is to be distinguished in its comatose form from *typhoid fever*, and in its *algid* type from *yellow fever*. The presence of the plasmodium and pigment in the blood are the distinctive features to be carefully sought.

IRREGULAR FORMS OF MALARIAL FEVER.

It sometimes happens that the paroxysm in intermittent fever omits one or more of its stages. Especially is this the case with the chill in which event the disease has received the characteristic name of “dumb ague.” Frequently, however, what receives the name of “dumb ague” is something altogether different. The “malarial cachexia,” for instance, is sometimes spoken of as “dumb ague.” Like malarial cachexia “dumb ague” is found among the older residents of a malarial district.

Quite often it happens that the malarial paroxysm consists of nothing but a state of *drowsiness*, which recurs at regular intervals and is very characteristic. The temperature in these cases is elevated, but not very high, 100° F. (37.8° C.) or perhaps 101° F. (38.3° C.); there may be *slight delirium*. Another irregular form is *intermittent neuralgia*, which is clearly malarial, the proof of it being the facility with which it is broken up by quinin. Usually there is no fever in this variety. The nerve commonly involved is one of the branches of the trigeminal. The intercostal nerves are also the seats of such an attack, giving rise to one of the forms of pain in the chest, but any nerve-trunk or its branches may be affected, as the sciatic or brachial.

The term *latent intermittent fever* is applied to a combination of symptoms affecting persons living in malarial districts—consisting in a weary, languid feeling, associated with want of appetite, headache, nausea, vomiting, constipation, and coated tongue. Sometimes the so-called “bilious attacks,” which exhibit the above symptoms in an aggravated form, especially the headache and vomiting, are malarial in their origin, and may be broken up with quinin. Such attacks may be called *malarial migraine*.

Irregularity of fever or chills, or both, may be caused by infection with more than one group of the same kind of parasite occurring at different times, or there may be infections of different kinds of parasite maturing at their own specified time.

MALARIAL HEMATURIA, OR HEMOGLOBINURIA, OR INTERMITTENT HEMATURIA—BLACKWATER FEVER.

This form of hematuria is the direct result of malarial poison. The first account of it in this country was published by George Troup Maxwell in the "Oglethorpe Medical and Surgical Journal," Savannah, Ga., volume iii. pages 12-18, July, 1860. While it is a very frequent symptom of the pernicious or malignant type of malarial fever, it also occurs as a symptom, and, indeed, sometimes the sole symptom, of the milder varieties of malaria, such as occur in the Middle States of the United States. I have met a number of these cases. Rarely are they accompanied by a chill, and there may be no symptoms whatever except the bleeding. More frequently there is a cold feeling, the tips of the nose and of the fingers become cold, and the lips become blue, immediately after which the urine is found to be bloody. Microscopic examination of the urine will recognize in some instances blood-discs, in others no corpuscles can be found. It is a *hemoglobinuria*.* The hemorrhage occurs daily or on alternate days, more rarely at longer intervals. Sometimes it is continuous, with exacerbations at regular intervals. In all cases of unexplained hematuria the blood should be examined for the malarial organism.

When a symptom of pernicious malarial fever, the condition is more apt to be hemoglobinuria than hematuria; it is more aggravated and more continuous, although still intermittent. It may also be associated with hemorrhages from the nasal and oral mucous membranes, and even from the stomach, which add much to the gravity of the case.

To such a grave form of malarial fever occurring in the Niger delta in Africa the name *blackwater fever* has been given.

CHRONIC MALARIA AND MALARIAL CACHEXIA.

Definition.—This is a condition which often supervenes in cases imperfectly or ineffectually treated, or in persons living in malarial districts where there is constant exposure to the cause and consequent repeated attacks.

Symptoms.—The most striking symptom of this condition is *anemia* of a peculiar kind. The incident changes in the blood have been referred to on page 72. The skin exhibits a dirty-yellow or sallow appearance, often erroneously characterized as "bilious," as though it were a form of jaundice, which it is not, although there may be sometimes slight jaundice also. Such persons have, in addition, deranged digestion. The tongue is pale, flabby, and coated, and the breath sometimes foul. The bowels are constipated. The hands and feet are cold, the circulation is generally bad, and the temperature is subnormal, though it may alternate with the feverish state. In consequence of the hydremic blood there is sometimes edema of the feet, and even general anasarca. The *spleen is enlarged*, often extending as low as the ilium.

Some very unusual symptoms are included in the symptomatology of this form of malaria—as, for example, *paraplegia* and *orchitis*. The former

* The presence of hemoglobin can be easily shown by making Teichmann's hemin crystals in the following manner: The earthy phosphates are precipitated, filtered out, and a small portion placed on a glass slide, and carefully warmed until completely dry. A minute granule of common salt is carried on the point of a knife to the dried mass and thoroughly mixed with it. Any excess of salt is then removed, the mixture is covered with a thin glass cover, a hair being interposed, and a drop or two of glacial acetic acid allowed to pass under the cover. The slide is then carefully warmed until bubbles begin to make their appearance. After cooling, hemin crystals can be seen by aid of the microscope. These, though often very small and incompletely crystallized, are easily recognizable by an amplification of 300 diameters. They are, chemically, hydrochlorate of hematin.

condition may be the result of deranged circulation in the spinal cord, but it is difficult to regard the latter as anything except a coincidence. A remarkable case of malaria with symptoms of disseminated sclerosis was reported by Dr. William G. Spiller in the "American Journal of the Medical Sciences" for December, 1900. The autopsy disclosed sclerosis of the right crossed pyramidal tract throughout the spinal cord, not intense, but unmistakable.

The *plasmodium* is found in this form of malaria also, and the *crescent* is said to be the form more or less characteristic of it. The recognition of the organism is of value in the diagnosis of this from other forms of anemia, although the history of the case and the presence of enlarged spleen are also important factors in diagnosis, especially as the plasmodium may elude detection altogether, and malaria still be present. It is to be remembered, however, that in leukemia there is also enlarged spleen, but the microscopic examination of the blood reveals at once in the latter disease the excess of colorless corpuscles.

Prophylaxis of Malarial Fever.—Much may be done to avert malarial infection. It is not considered possible for the organism to enter the system by the stomach or respiratory passages. This being established, prophylaxis must consist in measures to destroy the mosquito or escape its bite. To exterminate the adult mosquito is manifestly impossible. Yet it is not chimerical to look forward to the possibility of destroying the insect in the larval state as it exists in pools and ponds. While all the more common species of mosquito belong to the genus *culex* or genus *anopheles*, Ross has shown that up to the present only mosquitos belonging to the genus *anopheles* have been found to contain malarial parasites. The larvæ of this genus live, not in artificial collections of water, but in natural ponds in rural regions. Ross believes that, if future experiments show that malaria is confined to the genus *anopheles*, the task will be much more simplified, and there would be a chance of exterminating the whole genus in a given locality. In the meantime our prophylactic measures must consist in protecting against mosquito bites by netting, and in making the blood as uncomfortable a habitat for the plasmodium as possible by charging it with quinin. To this end a few grains of quinin, say five to ten (0.333 to 0.666 gm.), should be taken daily, especially by newcomers and by all residents at times. It seems pretty well founded, too, that the cause of malaria is more active after nightfall. This is not inconsistent with the mosquito theory. Hence, exposure at these times should be avoided. It is also a notion with residents in malarial districts that exposure while the stomach is empty is apt to invite the poison. This is probably erroneous. Should it be true, exposure while fasting should be avoided. In this matter, as in others, it may be necessary to give up a good many of our old notions, but until the new theories are thoroughly established it may be just as well to adhere to practices justified by experience.

Treatment of the Different Forms of Malaria.—The treatment of *intermittent fever* is preëminently by *quinin*. Not only does it promptly break up the paroxysms, but it causes also the rapid disappearance of the plasmodium, which is responsible for them. The dose required varies, but fifteen to thirty grains (1 to 2 gm.) are usually sufficient for an adult. Sometimes larger doses may be needed in inveterate cases. It does not matter very much how the drug is administered, but there is a best way for each case. I prefer, as a rule, to give an hourly

dose of three to five grains, beginning long enough before the expected paroxysm to get the quantity previously decided upon into the blood at least two hours before the chill is expected. If the dose first selected fails, the second should be made larger. It is to be remembered, however, that quinin, like other drugs, acts more efficiently after a free aperient, while constipation decidedly interferes with its prompt and efficient action. Some prefer a mercurial, as eight to ten grains (0.05 to 0.666 gm.) of blue mass, or six to ten grains of calomel, but provided a free movement is secured, it does not matter much how it is accomplished. Having broken the paroxysm, it is well to continue the quinin for a few days in smaller doses, and to anticipate the seventh day subsequent to the last chill by another full dose of the drug, and to do so at intervals of seven days for some weeks. Under ordinary circumstances the freshly prepared pill of quinin made with aromatic sulphuric acid is to be preferred. This is easily soluble and is not so unpleasant to take as the solution, which is, however, more readily absorbed. The sugar-coated and gelatin-coated pills are not so certainly efficient, as they sometimes, especially with deranged digestion, pass through the bowel undissolved.

Some physicians prefer to administer quinin during the decline of the fever. This was the practice of Sydenham in giving the bark. Among modern physicians disposed to follow this method are Bacelli, A. Plehn, Maclean, Manson and other East Indian physicians; and in this country George Dock.

The treatment of the paroxysm itself is by measures calculated to combat each stage. During the chill, to satisfy the patient, artificial warmth should be supplied, though it does no good and the temperature is already a fever temperature; during the fever, if the temperature is above 102° F. (38.9° C.), the body may be sponged to reduce the heat, and during the "sweat" the patient should be carefully dried. If there be any reason why quinin should not be exhibited, the other alkaloids of cinchona, as cinchonidin, are equally effectual in doses about one-fourth larger. No substitute for cinchona or its alkaloids has ever been suggested which has stood the test of trial.

The treatment of *remittent fever* is essentially that of intermittent fever. It is in this form that the mercurial aperient is deemed especially valuable as a preliminary by those having wide experience in its treatment. The continued nature of the fever, and the tendency to a typhoid state which often develops, demands a liquid diet, with the careful addition of stimulants.

The *pernicious forms* of malarial fever are treated by quinin, as are the other varieties of the disease. In the congestive variety advantage must be taken of the first lucid interval to push the drug in very large doses. Sixty grains or more may be necessary, and advantage may be taken of rectal or even hypodermic injections, but abscesses are almost sure to occur if the latter be used. Extreme cases, however, demand extreme remedies. Soluble salts should be used, such as the bisulphate, hydrochlorate, and hydrobromate, of which 15 grains (1 gm.), dissolved in distilled water, are a dose. Double this dose may be given. The bisulphate of quinin may also be administered hypodermically with tartaric acid, 30 grains (2 gm.) of the former to 5 grains (0.333 gm.) of the latter. The muriate of quinin and urea may also be given hypodermically in ten-, fifteen-, or twenty-

grain (0.666, 1, and 1.33 gm.) doses. It is especially commended by Solomon Solis-Cohen, who advises, as soon as the diagnosis is established, and without reference to the time of paroxysm, a single injection of from 10 to 15 grains (0.66 to 1 gm.) of the salt, dissolved in a syringe-ful (20 to 30 minims) of boiling water. Should a paroxysm recur at the following period, a second injection is given, and should further paroxysms occur, injections are given in corresponding number; otherwise but three injections are given during the first seven days, and two injections during the second seven days. My experience in the hypodermic use of this drug has been satisfactory from the therapeutic standpoint, but I have not escaped abscesses. It may also be given by the mouth in capsules in the same doses.

Even the intravenous injection of quinin has been recommended in intractable cases, and for this purpose the soluble bimuriate is most suitable. Fifteen grains (1 gm.) with one grain (0.666 gm.) of sodium chlorid are dissolved in two drams (8 c. c.) of distilled water and injected.

In addition to the use of quinin, prompt measures must be taken to combat all symptoms which add to the dangers of the situation—stimulants for the asthenia; artificial heat for low temperature; morphin hypodermically, to relieve the pain and allay nausea; cool sponging or bathing to reduce the temperature, and saline cathartics to relieve congestion in the comatose form.

The treatment of the *milder varieties of hematuria* is most satisfactory. The administration of quinin in almost any way, say three grains (0.19 gm.) every three hours for several days, will effectually break up the paroxysms, and its use in smaller doses for some time longer will prevent a return.

All practitioners, even those residing where it is most prevalent, are not agreed upon the treatment of the *graver forms* of malarial hematuria met in southern latitudes. While some still urge quinin, others strongly object to it and hold even that it precipitates hemoglobinuria. Only so long as sporulating parasites are present in the blood would they use it, and the actual presence of hematuria contra-indicates it. At most it must be used tentatively in doses as small as a grain, and if the urine reddens or a chill supervenes, they omit it. If well borne, the dose may be increased.

Treatment is otherwise symptomatic—usually eliminative and restorative. Elimination is obtained by water-drinking and salt solution ingestion, the latter by enteroclysis, hypodermoclysis, or even intravenous injection. The skin must be kept active by cautious doses of pilocarpin, by woolen clothing and avoiding draughts. In urgent cases pilocarpin may be cautiously used, but the hot pack is a safer measure. Morphin in small doses may be used to control vomiting, and for its general tranquilizing effect. Strychnin and diffusible stimulants, ammonia, brandy, and champagne, are often necessary. Strychnin may be given hypodermically. Stimulating diuretics are strongly disadvised.

It is in *chronic malaria* especially that *arsenic* becomes a useful remedy, Fowler's solution being the best preparation. It should be given in ascending doses. *Iron* is often advantageously associated with it, and for such a combination the solution of the chlorid of arsenic and the tincture of the chlorid of iron are especially suitable. Here, as elsewhere, I am disposed to believe that needlessly large doses of iron have been given and that the constipating effect of iron, so justly complained of, would be

obviated by giving doses little in excess of what can be absorbed. For it is this excess remaining in the alimentary canal that works the mischief. Five minims (0.333 gm.) of the tincture of the chlorid, combined with as many of the solution of the chlorid of arsenic, are a proper dose, but the arsenic should be increased until a slight puffiness of the face results. The carbonate of iron or the reduced iron sulphate may be given in doses not exceeding one grain (0.066 gm.). A modified Blaud's pill containing in addition to the carbonate of iron arsenic in 1-25 grain (0.0026 gm.) doses is a very efficient and convenient remedy. The administration of iron should be kept up a long time.

Quinin should not be omitted in this form of malaria, but there is no advantage in giving it in large doses. *Strychnine* and *mineral acids* are also useful remedies for the gastric derangement, while constipation may be treated by an occasional mercurial purge, say a couple of grains (0.132 gm.) of blue mass, to which may be added as much compound extract of colocynth, and as much extract of hyoscyamus, or 1-8 grain (0.008 gm.) of extract of belladonna.

Very popular in the hands of some physicians is Warburg's Tincture, and it does seem that it succeeds where quinin alone fails. Besides quinin, it contains aloes, rhubarb, and a number of aromatics. One formula omits the aloes, so that in prescribing one should say with or without aloes. It usually proves a powerful sudorific. It is given in half-ounce doses, repeated after two or three hours. The action is similar to that of antipyrin, phenacetin, etc.

YELLOW FEVER.

SYNONYMS.—*Febris flava*; *Bilious Remittent Fever* (Rush); *Kendall's Fever*; *Barbadoes Distemper*; *India occidentalis*; *Elodes icterodes*; *Typhus icterodes*; *Typhus tropicus*.

Definition.—Yellow fever is an acute infectious disease, characterized by a febrile paroxysm succeeded by a brief remission and a relapse. It is associated more or less constantly with jaundice, and tendency to hemorrhage especially into the stomach, whence the blood is vomited constituting "black vomit." Neither jaundice nor black vomit is essential to the disease.

History.—The birthplace of yellow fever is unknown. It appeared in Barbadoes in 1647; prevailed in Jamaica in 1671; at St. Domingo in 1691; Pernambuco, in Brazil, from 1687 to 1694; in Martinique in 1690; in Boston Harbor probably in 1692; Philadelphia and Charleston in 1692; Rocheford, France, in 1694; and Philadelphia again in 1699, when a severe epidemic prevailed. Philadelphia was again visited in 1741 and 1762; New York in 1791, and Philadelphia in 1793, during which time there reigned one of the most frightful epidemics history records, 4040 dying out of a population of 40,000. After 1793 the disease prevailed more or less every year in the United States until 1805. From 1805 to 1820 the epidemics were limited or only isolated cases occurred, until 1820, when Philadelphia was again severely attacked. After 1820 there was a period of comparative immunity, but not without cases and small epidemics in various cities of the United States, until 1853, when there raged a violent outbreak through the southern cities of the Union. In New Orleans alone in that year nearly 8000 died. In 1867 and 1873 there were other epidemics of moderate severity, and in 1878 another severe epidemic appeared, chiefly in Louisiana, Alabama, and Mississippi, during which nearly 1600 died. This was the last severe epidemic. In 1897 there were several local outbreaks in the Gulf States. In New Orleans alone, between September 8 and December 11, there were 1902 cases, with 288 deaths, according to the Marine Hospital Reports.

Thus, it is in a sense an American disease, and except in Spanish ports it has been limited in Europe to ports to which it has been carried. its spread from these having been also prevented. It is, however, endemic at the present day on the west coast of Africa as well as in the West Indies.

Distribution.—John Guitéras makes three areas of infection: (1) The focal zone, in which, up to 1901, the disease was never absent, including Havana, Vera Cruz, Rio de Janeiro, and other Spanish-American ports. (2) Perifocal zone, or region of periodic epidemics, including the ports in the tropical Atlantic, in America, and Africa. (3) The zone of accidental epidemics, between the parallels of 45 degrees north and 35 degrees south latitude.

A very interesting fact in connection with yellow fever is its limitation to the sea and the seacoast, as it rarely invades interior cities or altitudes higher than 1000 feet (300 meters).

Etiology.—The analogy between yellow fever and the other forms of contagio-infectious disease, in its origin, spread, and conditions, renders it more than likely that it, in common with them, is the result of a specific organism. Domingos Fréire, of Brazil; Carmona, of Mexico; Gibier at Havana, and others have described organisms as possibly responsible, all of which have been rejected. In 1889 Surgeon General Sternberg, U. S. A., discovered a bacillus in the tissues of yellow fever patients, which he called bacillus X. In 1896 Sanarelli,* Director of the Institute of Experimental Medicine at Montevideo, isolated a bacillus, which he called *bacillus icterodes*. These, Sternberg says, are identical, but the late Dr. Walter Reed and Dr. James Carroll, after a careful study, concluded that the bacillus X belongs to the colon group, and the bacillus icterodes to the hog cholera group.†

Notwithstanding the fact that Sanarelli's bacillus has been found by a number of observers in from thirty-three per cent. to fifty per cent. of cases examined, conclusive evidence that it is the specific germ of yellow fever is wanting. On the other hand, the most recent studies of Reed and Carroll go to show that it is probably an ultra-microscopic organism in the blood of the infecting person.‡ As to the propagation of the disease, the same observers with Aristides Agramonte, all of the United States Army Medical Department,§ have placed the mosquito theory of the origin of yellow fever on so substantial a basis that it would seem that further discussion of other theories may as well be laid aside. This theory, which, it will be remembered, makes the mosquito the host of the unknown parasite of yellow fever, was first advanced by Carlos J. Finlay, of Havana, as far back as 1881,|| but made little impression. The studies of Reed and his colleagues, made in the island of Cuba in 1900, are most convincing. They included two divisions: First, the exposure of immunes to the bites of mosquitos which had bitten yellow fever subjects; and second, exposure of the same to fomites by handling and sleeping in clothing saturated with the discharges of yellow fever patients. Their conclusions are as follows: 1. The mosquito—*Stegomyia fasciatus*—serves as the intermediate host for the parasite of yellow fever. 2. Yellow fever is transmitted to the non-immune individual by the bite of a mosquito that has previously fed on the blood of those sick with this disease. 3. An interval of about twelve days or more after contamination appears to be necessary before the mosquito is capable of conveying the infection. 4. The bite of the mosquito at an earlier period after contamination does not appear to confer any immunity against a subsequent attack.

5. Yellow fever can also be experimentally produced by the subcutaneous injection of blood taken from the general circulation during the first and second days of this disease. 6. An attack of yellow fever produced by the bite of a mosquito confers immunity against the subsequent injection of the blood of an individual suffering from the non-experimental form of this disease. 7. The period of incubation in thirteen cases of experimental yellow fever has varied from forty-one hours to five days and seventeen hours. 8. Yellow fever is not conveyed by fomites, and hence disinfection of articles of clothing, bedding, or merchandise supposedly contaminated by contact with those sick with the disease is unnecessary. 9. A house may be said to be infected with yellow fever only when there are present within its walls contaminated mosquitos capable of conveying the parasite of this disease. 10. The spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitos and the protection of the sick and well against the bites of the insects. 11. While the mode of propagation of yellow fever has now been definitely determined, the specific cause of this disease remains to be discovered.

It is evident that many of the older views, so long accepted, must be given up if this theory is adopted. On the other hand, many well-known facts are more satisfactorily explained. Among these is this, that freezing weather terminates the activity of the disease, but does not destroy it.

Yellow fever attacks all races, both sexes, and all ages except the very young. Yet it is through the young that the disease is maintained in a native population, because protection is secured by a previous attack or long residence in a locality in which it is endemic, and it is the young who, as they grow up, furnish the pabulum for fresh cases. The negro and the creole, although not immune, are comparatively so. More males are attacked than females, because of their frequent exposure. Strangers are especially liable.

Morbid Anatomy.—Intense *yellow coloration* and *hemorrhagic extravasations* under the *skin* are present. The yellow coloration is due to a mixed hepatogenous and hematogenous jaundice. The serum of the blood is red-tinted, because of its containing dissolved hemoglobin. The *liver* is the organ which has always been regarded as exhibiting the most characteristic change. Yet this is not always so. It becomes ultimately fatty, when its color resembles the yellow of admixed coffee and milk—a *café au lait* appearance—as contrasted with the more bronzed appearance of the liver of remittent fever. Earlier in the disease the organ may be slightly enlarged from hyperemia. It may be a nutmeg liver. The liver-cells present various stages of fatty degeneration, with necrotic masses in and between the liver-cells, described by George M. Sternberg. The *gall-bladder* is generally empty. The kidney may exhibit cloudy swelling or even acute nephritis, and pale, fatty areas may be seen at the bases of the pyramids. Various bacteria are found in the liver and kidney.

The *stomach* after death contains more or less of the “black vomit,” which is a mixture of transuded serum and altered blood pigment. The mucous membrane of the stomach is hyperemic and more or less swollen, and there are blood extravasations.

Surgeon Eugene Wasdin,* in a paper on the postmortem findings of yellow fever, says the morbid appearances postmortem cannot be regarded as sufficiently distinctive to admit a diagnosis from them alone.

* “United States Marine Hospital Reports for the Fiscal Year 1898.”

Symptoms.—Yellow fever has a *period of incubation* of from twenty-four hours to five days, very rarely exceeding the latter. It is usually three or four days. (See Reed and Carroll's conclusions.) After this follows the *stage of invasion* or *febrile stage*, with sudden onset and generally a chill, promptly followed by headache and severe pain in the back and limbs. The patient may be seized at any time, day or night. Surgeon R. D. Murray,* of the United States Marine Hospital Service, emphasizes the fact that yellow fever *usually begins at night* when the patient is relaxed, while malarial fever attacks him more frequently when at work. The fever rises rapidly to 102° F. (38.9° C.) and as high as 105° F. (40.5° C.). The pulse corresponds. The skin feels hot and dry, but less pungently so than in typhus. Even on the first day the face is flushed, the eyes are injected, the lids perhaps slightly tumid, the tongue furred but moist, the throat sore, the bowels constipated, the urine is scanty and often albuminous, though albuminuria does not generally appear until the evening of the third day. So, too, at this early stage there may be slight *jaundice*, and Guitéras says this "early manifestation of jaundice is undoubtedly the most characteristic feature of the facies of yellow fever." There may be nausea from the beginning, but it is not until the second or third day that it is aggravated and the characteristic "black vomit" makes its appearance. This resembles an infusion of coffee, and deposits a sediment comparable to coffee grounds, and which consists of broken-down red corpuscles and hematin. In the worst cases the vomited matter may be tar-like in appearance and consistence. On the other hand, "black vomit" is not always present, being generally confined to the severe cases. In some, the vomited matter is watery or bilious. *This stage lasts from a few hours to two or three days.*

Then follows the *second stage*, or *stage of calm*, in which there is a decline in the fever and of the other symptoms generally. This may be the beginning of convalescence in the mild cases. But in severe cases this stage is of short duration,—*from a few hours to one or two days.*

Then the *third stage*, or *stage of febrile reaction*, sets in, lasting one, two, or three days. The temperature now rises again, *although the pulse may continue to fall*; the nausea and vomiting return—the latter becomes hemorrhagic and may be accompanied by abdominal pain. Black and offensive stools occur. Jaundice, if not previously present, now makes its appearance; the tongue becomes dry and brown, and there may be bleeding of the gums—indeed, from all the mucous membranes. To albuminuria may be added *hematuria*. The strength rapidly fails, the pulse grows weaker, there is nervous trembling, suppression of urine, mental wandering, convulsions or stupor, and death.

Such, however, is not always the termination, even when there has been "black vomit." The symptoms may all gradually subside and the patient recover, although the jaundice may persist for a long time. In mild cases the calm stage, as stated, may be succeeded by convalescence.

Guitéras† regards as the three characteristic symptoms of yellow fever: First, the *facies*, including especially early jaundice. Second, *albuminuria*, which, he says, is rarely so early in other fevers, unless of an unusually severe type. "Even in the mild cases, that do not go to bed—cases of 'walking yellow fever'—on the second, third, or fourth day of the disease albuminuria will show itself," though it may be quite transi-

* "Marine Hospital Reports," 1890, p. 303.

† "Diagnosis of Yellow Fever," "U. S. Marine Hospital Reports for the Fiscal Year 1898."

ent. Third, a peculiar *slowing of the pulse*, with a steady or even rising temperature. This symptom was first pointed out by Faget, of New Orleans. It is noted more particularly on the second or third day, when the fever is still keeping up, that the pulse begins to slow, dropping as much as twenty beats, while the temperature has risen 1-2° to 2°. On the evening of the third day there may be a temperature of 103° to 104° F. (39.4° to 40° C.), with a pulse running from 70 to 80. During defervescence the pulse may become still slower—down to 50, 48, 45, or even 30.

Diagnosis.—The three characteristic symptoms of Guitéras above pointed out should be borne in mind, viz., facies, early albuminuria, and slow pulse. As to differential diagnosis, yellow fever is most likely to be confounded with severe fever of *bilious or malarial remittent* type. Indeed, the resemblance is sometimes very close, especially when the latter is accompanied by hematuria. But the remission occurs earlier in remittent fever and the chill is of much longer duration, while the presence of Laveran's plasmodium in the blood settles the question in favor of the latter. *Acute yellow atrophy* of the liver is a disease more insidious in its approach and less febrile. The urine in acute yellow atrophy is loaded with bile.

Relapsing fever resembles yellow fever only in the symptoms of the relapse, but this occurs much earlier in yellow fever. The similarity of the mild forms of yellow fever to *thermic* fever has been emphasized by Guitéras.

As to *dengue*, or break-bone fever, increased importance has recently attached to the diagnosis between this disease and yellow fever because of the dispute as to whether certain cases in the epidemic of 1897 in the Southern United States—as at Galveston, for example—were cases of dengue or of yellow fever. The question is one which presents difficulties, for both jaundice and hemorrhage, including black vomit, have been in the past credited to dengue, while in the disputed cases black vomit, at least, was wanting. In favor of yellow fever were the authoritative names of Guitéras and H. A. West, of Galveston. The following table of contrasted symptoms was kindly prepared for me by Dr. West:

YELLOW FEVER.

1. One febrile paroxysm, characterized by a steady rise and lasting usually about three days. The temperature rises rapidly, the acme is often reached within a few hours from the onset.

2. The pulse rate is characterized by abnormal slowness and want of correspondence with the temperature; while the latter is rising from three to four degrees the pulse continues to diminish in frequency.

3. There are cutting pains through the forehead, the eyes ache, the muscles of the back, loins, thighs, and calves are sore and often ache severely, even in mild cases. The pain is muscular rather than articular.

4. There is no glandular involvement.

5. The face is turgid, not infrequently a dusky red. The upper eyelid is often swollen. The appearance is that of typhus or of measles before the eruption, with the addition of slight or well marked

DENGUE.

1. Usually one febrile paroxysm, but sometimes two, a steady rise of temperature until the acme is reached; a short stadium, followed by a remission, then not infrequently a second rise. Duration four to eight days.

2. The pulse usually increases in rapidity with rise of temperature, though an abnormally slow pulse may sometimes be observed.

3. Headache is more or less intense, pains in the limbs and back are severe and apparently involving the bones and joints. The latter are not only painful and stiffened, but in many instances swollen.

4. The lymphatic glands are enlarged with varying degrees of frequency in different epidemics.

5. The face is generally flushed, the eyelids swollen, the eyes injected and watery; there may be a slight jaundice, but this symptom is extremely suspicious of yellow fever.

jaundice. The conjunctivæ are congested and shiny with a slight yellow tinge, the eyes sometimes intensely red and sensitive to light. The jaundice becomes more distinct after the first or second day, the skin showing the same combination of capillary stasis with an icteroid hue as the eyes. As the case progresses, jaundice may become intense.

6. The tongue is whitish in the center, with red tip and edges, and is pointed; gums swollen and disposed to bleed. Epigastric tenderness and pain, nausea and vomiting are common; in the stage of depression black vomit is not infrequent; it is alarming and often of fatal import.

7. Eruption absent, or extremely rare and insignificant.

8. Urine scanty, albumin usually found within seventy-two hours; there may be only a trace in the evening urine. In the second stage albumin may be abundant and accompanied by all the evidences of a severe nephritis, the presence of casts, hematuria, disposition to anuria and uremia. *In every severe case nephritic complications dominate the clinical picture.*

9. Tendency to hemorrhages common, from nose, gums, bowels, uterus, kidneys, and stomach, the last often fatal.

10. Disease often fatal.

11. One attack protects from another.

12. Not protective against dengue.

6. The tongue at first is covered with a white fur; it is swollen and the edges are red, and as the case progresses the coating increases in thickness and becomes a dirty yellow. In many cases there is nausea, but vomiting is rare.

7. An eruption occurs in quite a large number of cases; it may be a simple erythema or resemble that of scarlatina, measles, lichen, or urticaria.

8. The urine, except in rare instances, is free from albumin; if present at all, it is evanescent. There is no evidence whatever that serious kidney complications belong to the pathology of dengue.

9. Hemorrhages from mucous membranes, nose, gums, intestines, uterus and kidneys not infrequent, but rarely of serious import.

10. Prognosis proverbially favorable.

11. One attack does not protect from another.

12. Not protective against yellow fever.

Prognosis.—Yellow fever is a grave disease, and in its severe forms one of the most fatal of the infectious diseases. The mortality ranges from 15 per cent. to 85 per cent. Among the dissipated, the worn-out, the poor, and in hospitals the mortality is higher; it is less in the colored race. "Black vomit" is not necessarily a fatal symptom. Many malignant cases terminate in a couple of days. Modern studies go to show the ravages of yellow fever will be greatly diminished in the near future, emphasized by the statement of Dr. Guitéras at the Sanitary Conference of American Republics, held in Washington, D. C., in December, 1902, to the effect that "not a case of yellow fever has originated in Cuba for fourteen months."

Treatment.—There is no specific treatment for yellow fever, and the symptoms are to be met as they arise. The practice quite general in the Southern United States to give an initial dose of castor oil is justified. Some prefer calomel five to ten grains (0.33 to 0.66 gm.); others compound cathartic pills, one, two, or three at a dose followed, if necessary, by a saline such as cold citrate of magnesia, Epsom salt, or Glauber salt. The last is preferred by some who have had the longest experience. These measures are followed by efforts to cause perspiration, in which the hot foot-bath is included. Quinin is not recommended by those of wide experience for any specific effect, though it may be given for its antipyretic effect. The latter is, however, better accomplished in the early stages by the coal-tar derivatives antipyrin and acetanilid. Seven and one-half grains (0.5 gm.) may be given hourly until relief is afforded. Recent views as to the etiology

of the disease would seem to justify a return to quinin for its original purpose. We may seek to stop vomiting by ice internally and externally and hypodermic injections of morphin, by cold dry champagne and cold effervescing waters. Food should be withheld for from three to five days, and then be of the simplest kind, of which a mixture of equal parts of milk and Vichy is the type. The hemorrhagic tendency may be combated by astringents, including iron. Washing out the rectum by warm soap and water and enemas, carried high up in the bowel, is highly recommended by Marine Hospital Surgeon H. D. Geddings.* Two or three pints must be used. Normal salt solution may be thus used with a view to its being retained and absorbed.

The failing strength is to be supported by alcohol, strychnin, and digitalis; the high temperature reduced by sponging and cool baths. Nutrient enemas are to be relied on when vomiting is uncontrollable.

The following line of treatment laid down by Surgeon-General Sternberg appears to have been especially satisfactory in cases treated in United States, Cuba, and Brazil, with a mortality, according to Carroll, of only 7.3 per cent. In addition to sodium bicarbonate 7 1-2 grains (0.5 gm.), mercury bichlorid 1-60 grain (0.001 gm.) every hour, he advises a hot mustard foot-bath during the first 24 hours, cold sponging, cold applications to the head, protection from currents of air, sinapisms over the stomach and lumbar region, the promotion of perspiration, withholding of food during the first three days, and stimulants, in the form of iced champagne or good brandy, after the fourth day. If the stomach be irritable he advises milk and lime water, and if these do not agree, nutrient enemas. Later on he allows milk punch, ale, porter, etc.

Good judgment should be exercised in discriminating against the over-use of drugs.

Prophylaxis is more efficient than direct treatment, but modern etiology has overthrown rules formerly supposed well established and resolved it chiefly into (1) Guarding non-immunes against infection by the mosquito. (2) Screening the house of the infected person against the insect in order to prevent the spread of the disease. (3) The destruction of as many mosquitos as possible, by drainage, by covering breeding places with insecticides and larvicides. Among these may be mentioned tobacco leaves, chrysanthemum powder, the anilin dyes, and petroleum. (4) Depopulation of infected places—that is, the removal of all susceptible persons whose presence is not necessary for the care of the sick.

Serum Treatment.—Recent attempts at protective inoculation have not been followed by satisfactory results in yellow fever, though success for this treatment was claimed by W. L. de Humboldt as far back as 1854, Caromon in 1881, and Fréire in 1884. Sanarelli has used the "antiamarylic" serum of a horse inoculated with gradually increasing doses of the icteroid bacillus for eighteen months. He treated eight cases subcutaneously, of whom two died. He also treated fourteen cases by intravenous injection, of whom four died.†

DENGUE.

SYNONYMS.—*Break-bone Fever; Dandy Fever.*

Definition.—Dengue is an epidemic, infectious, possibly contagious disease, characterized by paroxysms of extreme pain in the joints and muscles, accompanied by fever and sometimes eruptions on the skin.

Historical.—Dengue was recognized as a distinct disease in the latter part of the eighteenth century, first in Spain in 1764–68. It prevailed in Cairo and Java in 1779. In 1780 an epidemic prevailed in Philadelphia, which was described by Benjamin Rush under the name of bilious intermitting fever. In 1824 it prevailed in Calcutta, in 1827 and 1828 in Charleston, Savannah, and in New Orleans, U. S., and in the West Indies, and was described by the late Professor S. H. Dickson, then of Charleston. Since then there have been numerous epidemics, for the most part south of the thirty-second parallel of latitude. It is said that in Galveston, Tex., in 1897, 20,000 were attacked in two months.

Etiology.—J. W. McLaughlin, of Texas, has found in the blood of a dengue patient a micrococcus, which he holds accountable for the disease, but the effect of inoculations requires to be studied. Analogy would lead us to suspect such an organism, while experience justifies a like conclusion. Dengue spreads, as do diseases thus caused, by the routes and means of travel. It attacks both sexes and all ages, regardless of season, although warm climates are its natural habitat, and it is rather more common in summer. It is not usual to have more than one attack. No morbid anatomical changes have been found associated with the disease.

Symptoms.—Dengue is usually sudden in its onset, after a *period of incubation* lasting from three to five days, at the end of which there may be some *sense of discomfort* (more frequently there is not), *headache*, and even *chilliness*. Suddenly, often at night, the patient is struck with *pain* in the muscles and joints, and especially the muscles of the back and loins. The pain is searching, as though extending into the bones themselves. The small as well as the large joints are affected, and the pain is aggravated on motion. The suffering is extreme, and it may be said that the patient is literally racked with torture.

Simultaneously there are *headache* and *fever*, the former severe and the latter quite high, rising rapidly to 102°, 103°, 105° F. (38.9°, 39.4°, 40.5° C.), and even 106° or 107° F. (41.1° or 41.6° C.), reaching its maximum from the second to the fourth day, then declining, reaching the normal about the fifth day. The face is flushed, the conjunctivæ are congested, commonly less so than in yellow fever; the pulse is frequent, 100 to 120, rising and falling with the fever. *Delirium is not a marked feature*, save in children. The *tongue is coated and red at the tip and edges*, there are *loss of appetite*, *slight nausea*, and extreme *thirst*, *scanty urine*, and *constipation*; at times, however, the urine is copious and clear. *Hemorrhage* from the nose and gums has been noted, and both Eugene Foster and D. C. Holliday have seen *black vomit* similar to that of yellow fever; and in one case copious hemorrhage from the bowels, which persisted three months and terminated in death, was observed.

The paroxysm lasts *three or four days*, at the end of which the temperature falls, the pain subsides, and a short period of comparative comfort, though one also of great prostration, succeeds that of great suffering. It is during this remission that an *erythematous rash* makes its appearance on the face, neck, and shoulders, and thence over the whole body in two or three days. At the same time the *lymphatic glands* at the back of the head

and neck, in the axillæ and groins, swell, with some return of fever. The eruption is not constant or always uniform. It lasts from a few hours to a couple of days, when it subsides with the beginning of the second febrile movement, which is milder and shorter, after which true convalescence sets in. The eruption may also reappear, though rarely.

Diagnosis.—On account of the joint involvement, associated, as it often is, with redness, dengue has not inexcusably been mistaken for *acute rheumatism*; but the decided remission in two days, the altogether short duration of the disease, and its epidemic character, should soon extricate the physician from such confusion. The absence of any glandular swelling or eruption in rheumatism and the more close limitation of the pain to the joints aid in the discrimination.

After rheumatism, influenza is perhaps the next disease with which dengue may be confounded. It, too, is epidemic, and is attended often by extreme and sudden muscular pains, but the sudden intermission characteristic of dengue does not occur in influenza, nor does the eruption or glandular swelling.

The resemblance of dengue to *yellow fever* has been referred to under the latter disease, where, too, the two conditions are contrasted.

Prognosis.—Notwithstanding the extreme suffering, recovery is the invariable rule.

Treatment.—Nothing can be done to cut short the disease. The most satisfactory method to control the pain is by the hypodermic injection of morphin and atropin. One-fourth grain (0.016 gm.) of the former and 1-150 grain (0.00044 gm.) of the latter may be given, supplemented by phenacetin and antipyrin, in doses of ten grains (0.66 gm.) of the former and five grains (0.33 gm.) of the latter, every two hours, when the hypodermic injection may be repeated if relief has not been obtained. The coal-tar derivatives are also the best remedies for the fever, but they may be supplemented by sponging with cool water, or the cold bath in extreme cases. Prostration must be met by alcoholic preparations.

CHOLERA.

SYNONYMS.—*Cholera asiatica*; *Cholera algida*; *Cholera maligna*; *Cholera infectiosa*; *Epidemic Cholera*.

Definition.—Cholera is an acute infectious disease caused by the invasion and toxic action of the comma bacillus or spirillum of Koch. It is characterized especially by vomiting, purging, painful cramp, and collapse.

Historical.—Cholera is a disease long endemic in certain localities in India, whence it has made periodical visitations to Europe, and in 1831-33 for the first time to North America. It invaded the United States in 1832 by two channels of immigration—first, from Great Britain by way of Quebec and the Great Lakes, reaching the then limits of settlement, the military posts of the upper Mississippi; second, by way of New York. In 1835-36 another visitation occurred, and in 1848 another by way of New Orleans and the Mississippi Valley, extending even to California. In 1854 a severe epidemic raged through the United States, for which immigration was also responsible. In 1865 Arabia and Egypt were severely visited in the spring, Constantinople in July, and thence all Europe. In 1866 it again appeared in Egypt, spread over all Europe, reaching the United States the same summer, during which there were quite a number of cases, some of which came under the observation of the author in the Philadelphia Hospital. An extensive outbreak prevailed in Europe in 1884, extending to Italy, Spain, and France, but it did not reach the United States.

Much more serious than any of the more recent epidemics was that of 1892, which

started in March or April in the northwestern provinces of India, attacking with great violence the pilgrims at the great Hurdwar Fair, near the source of the Ganges, and extending thence through Cashmere and Afghanistan to Persia, where it arrived in May or June. Thence it crossed the Caspian Sea and spread rapidly through European Russia into Prussia, seating itself most stubbornly and savagely in Hamburg in August. Havre, Antwerp, Berlin, Vienna, and especially Budapesth in Hungary, were also visited. A few cases occurred in Southampton, London, and Liverpool, and it reached New York Harbor in September, 1892. A few cases were also reported in New York City, but there was no further spread.

Etiology.—It is now generally acknowledged that cholera owes its existence to the comma bacillus or spirochæta, a semispiral rod-bacillus discovered by Koch in 1884. It is thicker, but not more than half so long as the tubercle bacillus. Sometimes, by the apposition of two bacilli, an S- or a corkscrew-shape is produced. Its multiplication is favored by heat, moisture, and filth. It is easy of destruction, even by weak acids and a temperature of 140° F. (60° C.). It can produce cholera only when it is taken in by the stomach, where, however, a normal gastric juice is always able to destroy it, while weak digestion induces a vulnerability that is promptly availed of by the bacillus, which quickly passes into the intestine, where the alkaline reaction of the secretions favors its development in enormous numbers. Bacilli are rarely found in vomited matters, but are numerous in the fecal discharges, and are found in the intestines after death. They may invade the follicles and intestinal wall, but some time is required for this, and such invasion does not occur in cases speedily fatal.

Medium of Infection.—Drinking-water and contaminated food are the acknowledged media through which the bacillus is commonly introduced into the human organism, but it may be conveyed in clothing or food, on the hands, and may even enter the mouth while floating in the air. The postal service is regarded as a means of infection. It frequently follows in the train of moving masses of human beings, such as emigrants and pilgrims, but it prefers the sea-level and lower altitudes, especially less than 1000 feet (30.5 meters) above the sea.

While at the present day the views of Koch as to the origin and spread of cholera are largely dominant, it should not be overlooked that an authority so high as that of Pettenkofer, of Munich, still holds that the germ of cholera develops in the soil-water of the earth during the heated months, and rises in the atmosphere as a miasm. He claims that the conditions peculiarly favorable to its development are a low-ground water, associated with porosity, moisture, and a contamination with organic matter, especially sewage. A. Rubino, in his article in "Sajous' Annual," volume ii., 1899, says that both theories are in accordance with fact, and Asiatic cholera must therefore be regarded as a contagious and miasmatic disease.

As stated, anything that enfeebles digestion favors its permanent lodgment and multiplication. Hence, general ill-health, fatigue, the alcoholic habit, depression of spirits, fright, or anxiety, any one or all may be predisposing causes. All ages and sexes are liable to be infected, but young children seem most vulnerable.

Morbid Anatomy.—The appearance of a man dead of cholera may present no peculiarity. More commonly, there is a shrunken aspect of the whole frame, the skin of the exposed and non-dependent parts is gray or ashen hued, while the dependent portions are livid. The eyes are deeply sunken, the temples hollow, the nose is pinched, and the skin clings closely to the bones beneath it. The appearances of such a body, in brief, are those of a wasted cadaver long immersed in the pickling vats of the dissecting room.

Very striking are the postmortem elevations of temperature and the phenomena of postmortem muscular contraction. The former has reached 109° F. (42.8° C.) and higher. The latter include movements of the lower jaw, rotation of the eyes, contraction of the arms and legs, sometimes startlingly life-like.

On section of the body the subcutaneous tissue is found dry, the blood in the vessels thick and dark. The condition of the stomach and bowels differs somewhat with death at different stages of the disease. If death takes place early the *stomach* is commonly, but not always, filled with a turbid liquid grayish-white in color, resembling rice water. In this the microscope may recognize columnar epithelial cells, isolated and in flakes; also the remnants of partially digested food, such as disintegrating muscular fasciculi and oil globules. The *mucous membrane* of the stomach appears *congested*, and the course of the larger vessels can be readily traced in consequence of their being full of thick blood. A *papillated appearance* ascribed to enlargement of the solitary follicles is often present. The epithelium is detached in places; in others, intact.

The mucous membrane of the *small intestine* may also be much congested; the bowel is filled with rice-water fluid. On its surface lie numerous patches or flakes of detached epithelium, while the papillated appearance produced by the enlarged lymphadenoid follicles is everywhere present. The villi are largely denuded of epithelium, but in places they are intact.

If death takes place during imperfect reaction, the gastro-intestinal *mucous membrane* is still more *congested* and dark-red in color from hyperemia and *blood extravasation*. At such times, too, the solitary glands are conspicuous and cause also a *papillated appearance* even more striking than that in the stomach. Peyer's patches may also be raised, and the same denudation of epithelium from the villi and elsewhere is present. The signs that suggest an inflammatory process are a slight cellular infiltration of the intestinal walls and the enlargement of the solitary follicles; also, at times, a diphtheritic exudate.

The *liver* is natural in size, but may be congested and darker hued than in health, while the cells exhibit cloudy swelling, and in places small areas of fatty change. The *spleen* is usually small, certainly not enlarged.

The condition of the *kidneys* is interesting, and varies with the stage at which the patient dies. If early in the disease the organ, superficially, is not much altered; it may be somewhat enlarged. The veins are slightly over-filled, but there is no marked capillary injection. There may be a few white or yellowish patches, where the epithelium is found compressed, cloudy, and fatty. The lumina of the tubes may, in places, be blocked with granular matter or well-formed casts, and there may be a few hemorrhagic foci, the changes starting from the pyramids.

If death takes place later, after reaction has set in, the kidney is enlarged. The changes are chiefly in the cortical substance, in which are seen grayish-white and yellow patches, alternating with normal-hued portions. In these altered places the tubes are opaque, with granular and fatty débris. Hemorrhagic infarcts may also be found in the cortical substance. The Malpighian capsules, with their included glomerular capillaries, are intact. These changes correspond in the two stages with the phenomena described by Cohnheim several years ago as the results of ligation of the renal artery,—the first to those following ligation of short duration, the second to those following ligation of long duration.

The *heart* is normal in size, but its walls flaccid. The right cavities are commonly filled with dark, liquid blood; the left cavities, empty.

In many instances the *lungs* also present an appearance more or less characteristic, being shrunken and small, lying back in the thorax, as though collapsed. Like the other tissues, they are empty of blood except in their dependent portions, which are the seat of hypostasis. They have been compared by Parkes to fetal lungs. Sutton found the two organs to weigh but 20 ounces (600 gm.), as compared with 45 ounces (1350 gm.), when death occurred after reaction had been established—that is, after the blood had again occupied the pulmonary artery and its branches. Collapse may be interfered with by adhesions, in which event it is only partial.

Such appearances could, of course, occur in death from hemorrhage and, after all, the only distinctive condition is the presence of the rice-water fluid in the stomach and intestine, or in both, containing the “comma” bacillus and desquamated epithelium. The latter, to which the earlier descriptions attached great importance, is now generally regarded as postmortem in origin. The flakes thus produced are also what the older authors described as patches of lymph.

Symptoms.—After a *period of incubation* ranging from thirty-six to fifty-six hours, rarely five days, the symptoms of cholera commonly present themselves sufficiently gradually to admit of arrangement into three distinct groups or stages:

1. The stage of preliminary diarrhœa.
2. The stage of collapse.
3. The stage of reaction.

The stages are by no means always recognizable, and the severity of the symptoms varies greatly, such variations being reasonably ascribed to the varying quantities or virulence of the specific poison. Mildness in a given case is no guarantee against virulence in another caused by it.

1. *The stage of preliminary diarrhœa** is characterized by moderate diarrhœa, which is characteristically painless, but may be associated with colicky pains. The stools are yellow or yellowish throughout this stage, and are alkaline in reaction. Nausea and vomiting are not usual in it, and the patient may feel but slightly indisposed. There is generally a feeling of restless discomfort and depression, to which headache may contribute. The temperature remains normal. The first stage may last for a week or longer, or for a few hours only, or it may be entirely absent.

2. *In the stage of collapse* the diarrhœa has become profuse. The discharges have lost their yellowish color and resemble thin gruel or rice-water. The fluid gushes out with great profuseness and apparent force. There may be griping or tenesmus, but more characteristic are the very painful muscular cramps, which usually begin in the fingers and toes and extend thence to the calves of the legs and abdominal walls. Vomiting, bilious at first, is soon added to the diarrhœa. The fluid vomited soon assumes the rice-water character, and gushes from the mouth as from the bowel, in enormous quantities.

Extreme weakness and exhaustion are by this time present. The skin is blanched and shrunken, the lusterless eyes are sunken and bounded below by great circles of blue. The nose is pinched, the lips are thin, the cheeks hollow, and the countenance pallid to bluish grayness. The extremities and entire body become clammy and cold, the superficial temperature falls 5° or

* To this stage the term *cholérine* has also been applied, but this word is now more commonly used to indicate a mild form of cholera.

6°, while that of the rectum rises to 103° and 104° F. (39° and 40° C.). Speech is husky, whispering, and labored. The pulse is feeble or frequent or absent at the wrist, and the patient appears to be dying. Even the heart-beat and sounds are almost gone, but the breathing continues. Through all this, consciousness may be maintained to the end or coma may supervene. Death commonly occurs in this stage.

On account of the scantiness of blood certain secretions cease and there is neither urine nor saliva, while power to perspire, and even the lacteal secretion in nursing women, remain.

A more close examination of the rice-water vomited matters and bowel discharges reveals flakes of epithelium, mucus, and granular débris, and, with sufficiently high powers and suitable preparation, the cholera bacillus together with numerous other bacteria. Occasionally a little blood is present. The fluid is albuminous and contains the salts of the blood, among which sodium chlorid is conspicuous. Sometimes, however, there may be no vomiting or purging, whence the term *cholera sicca*. In these cases, however, the stomach and bowels are commonly found containing the characteristic fluid after death.

This second stage is generally of shorter duration, commonly a few hours only, but it may be prolonged to twelve or twenty-four. The disease is sometimes ushered in with the symptoms of this stage. It has been ascribed to the action of a toxin produced by the bacilli, which, when absorbed, produces the systemic effects of this stage, but it is likely that the flux is the principal factor in its production.

3. *The stage of reaction* is characterized by the return of warmth and color, the latter more slowly, and the re-establishment of secretions. Especially favorable is the return of the urinary secretion. Along with these changes the vomiting and purging occur at longer intervals. Such improvement is, however, often delusive. The diarrhea may return, the collapse repeat itself, and the patient die. Or there may supervene *cholera typhoid*, a state characterized by a frequent, feeble pulse, dry tongue, delirium, and sometimes an *erythematous* or *roseolar eruption* on the extremities. This may end in recovery. Or there may be superadded symptoms of *nephritis*, including uremia, coma, and death. Or there may be *inflammation*, diphtheritic or catarrhal, of the bowels.

Diagnosis.—In the matter of the diagnosis it is well known that, so far as symptoms are concerned, cases of cholera morbus, *cholera nostras*, or sporadic cholera, as we may prefer to name it, have occurred with symptoms absolutely identical with those of true cholera, including the fatal termination.

There is one very important *etiological difference* between cholera morbus and true cholera, which is also of great diagnostic value, and that is that almost invariably cholera morbus is traceable to a severe and irritating exciting cause, such as a meal of indigestible fruits or vegetables, or imperfectly cooked or decomposing fish or shell-fish, while cholera comes on without any such cause, or succeeds trifling derangements of digestion, which in other than cholera seasons pass away without harmful results. As a rule, too, the symptoms of cholera morbus are much more severe at first than those of true cholera, and the substances first vomited are undigested articles that have acted as exciting causes, succeeded by green, bilious matter. The discharge from the bowels is first also of a more bilious character, and above all, the mortality is much less serious; indeed, recovery is the rule. Yet these dif-

ferences are not to be relied upon. (See, also, Appendix to Section on Cholera, p. 102.)

By bacteriological investigation only can a given case be identified with absolute certainty. The agglutinative reaction is the most ready method. It is similar to the Widal test for typhoid fever, and depends on agglutination of the bacilli in a culture of cholera vibrios, produced by the blood-serum of the infected case. Some hours are, however, necessary to complete such a bacteriological diagnosis. Further, such investigation can be made only by those who are expert and provided with proper facilities. Such expertness and facilities, moreover, are not found in the hands of the general practitioner, and the bacteriological investigation is, therefore, of limited application. Doubtless, should occasion demand, the authorities in the large cities, at least, will furnish the same assistance they now do in the case of diphtheria and typhoid fever.

As to the microscopic examination of the dejecta, which is more feasible for the practitioner, it may be said if the examination reveals a preponderance of curved bacilli, comma-shaped, and sometimes joined end to end, so as to form figures somewhat resembling the letter S, and again appearing in long threads, we may feel justified in considering the case one for careful study by bacteriological methods. Although there are found in the alimentary tract other bacilli, the morphology of which is much like that of the cholera bacillus, they are not numerous. The bacillus of Prior and Finkler, found in the stools of cholera morbus, while closely resembling the true comma bacillus of Koch, is larger and thicker. More easily distinguished are the cultures. The Prior and Finkler bacillus grows more rapidly and the shape of its culture is *sacchar*, while that of the cholera bacillus is *conical*. It also liquefies the gelatin much more rapidly.

How, then, shall we know a case of vomiting, serous diarrhea, severe colicky pain, followed by collapse, to be a case of cholera? In this country, where such a thing as endemic cholera is unknown, it goes without saying that any isolated case, even if fatal, cannot be one of true cholera unless there be traceable some connection with an acknowledged focus of cholera elsewhere. Second, such communication must have taken place within the period of incubation required for the development of the case, say within six days. Of course, such communication need not be a personal one. It may be by clothing, merchandise, and probably even letters.

These conditions being fulfilled, the patient suffering with the symptoms of cholera must, for the time being, be regarded as a case of the true disease, and isolated until the bacteriological investigation can be made, but the rapid occurrence of similar cases increases the probability of its being true cholera, and finally establishes its certainty. Yet local epidemics of cholera morbus do sometimes take place, severe and grave in character, due to local causes, and favored by extreme and long-continued heat. Thus it is still the question whether the epidemic of cholera that prevailed in Paris in May, June, and July, 1892, was true cholera or cholera morbus, and there seems much reason to believe it to have been the latter, notwithstanding the prevalence of true cholera elsewhere in Europe.

Symptoms similar to those of cholera arise from poisoning by corrosive sublimate, tartar emetic, arsenic, mushrooms, and ptomaines from various sources, but their symptoms are rarely confounded with those of cholera.

Prognosis.—The prognosis, always grave, varies with the stage of the

epidemic. It is well known that in the beginning a very large proportion of cases die, fully 80 per cent., but as the epidemic is prolonged the ratio of deaths to persons attacked grows less, the mortality falling to 30 per cent. or less. The habits and morals of the patient have an important influence. Intemperance and dissipation diminish greatly the powers of resistance, as do also fatigue, indigestion, fright, and fear.

Treatment.—The treatment of cholera is very appropriately divided into prophylactic and medicinal; the former, when properly carried out, being more effectual than the latter.

Prophylaxis.—In the first place, it has been shown that a certain degree of immunity from cholera is secured by a first attack. This was the conclusion of a collective investigation directed by the Academy of Medicine of Paris in 1884, and by Edward O. Shakespeare from information collected by him during his residence in Spain in 1885, appointed by the United States Government to investigate the subject. From this standpoint Ferran and others sought to secure immunity by inoculation of protective virus. The former, using a pure culture in bouillon of the *comma* bacillus, practiced the method in Spain during the epidemic of 1885, but a French commission appointed to investigate it reported unfavorably, and it fell into disuse, although Dr. Shakespeare in his "Report on Cholera in Europe and America" is inclined to believe there are possibilities in Ferran's method which make it worthy of further trial.

Gamaleia, Löwenthal, Brieger,* and Wassermann secured immunity in *animals*, by blood serum from others treated with injections of from 0.1 to 1 c. c. of cholera bacilli sterilized by heat, and G. Klemperer † obtained results which went to show that immunity could be conferred on *man* by the same treatment; also by the subcutaneous injection of the milk of immunized goats, though the immunity is considerably less by the latter than by the former. A. Lazarus showed (1892) that the blood of man, after recovery from an attack of cholera, has the property of protecting guinea-pigs from fatal infection when injected in very small quantities into the peritoneal cavity along with intraperitoneal injections of cholera vibrios. Issaëff, in 1894, confirmed the latter observation, but showed that the property was temporary. Lazarus regarded this effect antitoxic, R. Pfeiffer as the direct result of bacteriolytic or lysogenic action of the serum. Pfeiffer's studies on immunity from Asiatic cholera were published in conjunction with Issaëff in 1894. He showed that the destruction of living cholera bacilli quickly takes place in the peritoneal cavity of the immunized guinea-pig, if at the same time a minute quantity of the serum from an immune animal is injected. This constitutes Pfeiffer's "serum reaction," or phenomenon, and was demonstrated by him and Kolle for typhoid fever infection, and was one of the steps that led to recognition of the importance of the agglutinating reaction of sera. Up to the present time, apparently but three cases of cholera have been treated by subcutaneous injections of blood-serum from persons who recently suffered attacks of cholera. Of these, one died and two recovered.

The results of *protective* inoculations by cultures by M. Haffkine's

* Brieger's experiments were upon guinea-pigs, which he succeeded in making immune to virulent cultures of cholera bacilli. The method consisted in making intraperitoneal injections of comma spirilla cultures prepared in watery extract of calves' thymus or in beef-bouillon.—"Deutsche med. Wochenschrift," 1892, No. 31.

† "Berliner klin. Wochenschrift," 1892, No. 39, S. 969; "Med. News," Philadelphia, October 29, 1892, p. 496.

method are more practical. His researches at the Pasteur Institute, published in 1892, started with inoculation of the animal in the peritoneal cavity and exposure of the resulting exudate to the open air for several hours. A transfer of this to the peritoneum of another animal secures an "exalted" or "fixed" vaccine, the subcutaneous injection of which secures anticholeraic immunity, but with necrosis of the cutaneous tissues. This necrotic effect is removed by cultivating it at a temperature of 39° C. (102.2° F.) in an atmosphere constantly aerated. Successive inoculations result in an attenuation of cultures, which, injected under the skin of animals, even in an exaggerated dose, produces only a passing edema, while it leaves the animal immune to the "exalted" or "fixed" virus. The same harmlessness attends its inoculation under the skin of men, where the microbes die and disappear, setting free a substance which acts upon the organism and confers immunity on it. The same result follows the injection of their dead bodies only. Thus he was enabled to prepare vaccine, preserved in weak solutions of carbolic acid, which remains efficacious for six months, and may be used by persons without bacteriological training.

From the summary of cases, some 32,000 treated by his method in India during 1893-1894, published by M. Haffkine in January, 1895, we note a reduction of mortality from 6.51 per cent. in cases not treated to 3.8 per cent. of those treated. No other method has been tested by anything like as many cases, and though the correct treatment may not yet have been arrived at, it seems reasonable to believe that we are in close pursuit of one which is most promising of results. More recent inquiry into results of Haffkine's treatment in Calcutta during two years by Simpson ("Indian Med.-Chir. Rev.," July, 1896) shows a reduction of mortality of 72.47 per cent.

Until these processes are perfected we must be satisfied with a prophylaxis which, in point of fact, is little, if at all, less efficient in securing immunity than the most successful inoculation methods as yet suggested. By means of it cholera has been virtually kept out of England and the United States since 1873, though brought to certain ports where it has been held at quarantine. It consists mainly in the isolation of the patient and in certain precautions against the spread of infection by sterilizing the discharges. To this end:

1. The vomited matter and the discharges from the bowels are to be gathered in carbolic solution, 1 to 20, or chlorinated lime, 1 to 10, some of which should be in the vessels before it is used. After use, more should be added. The matter thus collected should be gently stirred and allowed to remain twenty minutes before being poured into the water-closet hopper. Where the excreta can be thrown into a pit, or even, as may be done in the country, on the manure pile, milk of lime, or what is the same thing, ordinary whitewash, is a very efficient and cheap medium with which to disinfect them.

2. After vomiting, the mouth of the patient should be rinsed with a solution of hydronaphthol, 1 to 5000, care being taken that none is swallowed. After each evacuation from the bowels, the buttocks, thighs, and anus should be washed with soap and water.

3. All body and bed linen soiled with the discharges should be immediately moistened with carbolic solution, 1 to 60, and removed in a covered vessel from the apartment, placed in a wash-boiler, and boiled for half an hour in a one per cent. solution of washing soda.

4. Napkins, towels, and table linen should be placed in a similar vessel or canvas bag for removal and similarly boiled.

5. All dishes, knives, forks, spoons, etc., used by the patient should be boiled after each meal in a one per cent. solution of soda.

6. The remains of meals should be thrown into a vessel containing milk of lime or whitewash, and removed at the end of the day.

7. Door-knobs are liable to be soiled by the hands of one carrying out excreta, and should be carefully washed and cleaned and sterilized, lest they, in turn, communicate the infectious material to another person handling them.

8. In case of death, the body, without being washed, should be wrapped in sheets wet in a solution of bichlorid of mercury, 1 to 1000, and allowed to remain until removed for prompt burial.

Special Directions to Nurses:

1. In like manner nurses of cholera patients should not hold any direct communication with others during attendance on such cases.

2. They should, under no circumstances, take their meals in the same apartment with the patient, and before leaving the room the hands should be cleansed with soap and bichlorid solution, and such portion of the dress as is liable to be soiled should be changed. The hands should be again rinsed in bichlorid solution, 1 to 1000, after leaving the patient's room. A very convenient plan is to wear a slip or "overall" with a hood to cover the hair, which can be easily thrown aside before leaving the room. A canvas slipper or overshoe, readily removed, should also be worn in the sick-room.

3. The food of the nurse should be wholesome and plain, freshly cooked, and served hot. No uncooked vegetables should be eaten. Milk should be boiled and, if desired, cooled before using. Cold drinks should be taken moderately, if at all. Coffee and tea may be taken hot.

4. Teeth should be cleansed after each meal, as the mouth affords a peculiarly favorable nidus for decomposing matters and a favorable nidus for the multiplication of pathogenic fungi. A daily bath in warm water, with the use of soap, should be taken by each nurse.

5. Care should be observed to keep the body from being chilled by drafts or other cool exposures, and to this end woolen underclothing should be worn.

6. Courage and cheerfulness are amply justified, because it is really almost impossible to take cholera if the above precautions are carried out.

The Treatment of the Attack.—The indications in the management of cholera, apart from isolation of the patient and the sterilization of the discharges, are, in the *first stage*, to check the diarrhea, combat the multiplication of bacilli, and neutralize their toxic influence. In the *second stage*, to relieve the cramp and pain and check the flux.

1.—The former is to be attained by the judicious use of opiates and acids on the one hand or opiates and antiseptics on the other; for antiseptics and acids can scarcely be used together, and the physicians must decide on which of the germicides he proposes to rely. Any of the mineral acids, such as hydrochloric, nitromuriatic, and sulphuric acids in doses of 10 to 15 minims (0.66 to 1 c. c.) of the dilute acid with as much tincture of opium or a corresponding dose of paregoric or deodorized tincture of opium

properly diluted, may be given every two hours. Or a lemonade of tartaric or citric or lactic acid, 2.5 drams to 1 quart of water (9.5 gm. to a liter), may be used in conjunction with the opiate. In addition, the rectum may be washed out by the warm solution of tannic acid in water or camomile tea, to be again referred to on page 101.

It has long been the practice to prescribe in cholera, as well as cholera morbus, a mixture of stimulating aromatics and irritants with opiates, and there is no doubt that in the early stages of cholera such combinations may be of value. The following is one of them:

℞ Tr. opii, Tr. capsici, Tr. zingib., Sp. menth. piper., Sp. chloroformi, Sp. camphoræ, Sp. vin. rect.,	}	aa f ̄ ss (2 c. c.) q. s. ad. f ̄ ij (60 c. c.)
---	---	--

M. Sig.—Teaspoonful in hot water or black tea every fifteen minutes until relieved.

Paregoric, in one-dram doses (4 c. c.), similarly administered early in the disease, is often sufficient to control the symptoms.

The following is the well-known cholera mixture or diarrhea mixture of Squibb, which is given under the same circumstances:

℞ Tr. opii, Sp. camphoræ, Tr. capsici, Chloroformi pur., Alcohol.	} aa f ̄ j (30 c. c.) f ̄ ij (12 c. c.) q. s. ad. f ̄ v (150 c. c.)
---	---	---

M. Sig.—Teaspoonful every hour or every two hours.

Instead of the acid solutions, antiseptics may be given for the same purpose. Of these, salol is a favorite, and may be given in doses of 10 to 15 grains (0.66 to 1 gm.) every two or three hours, and it may be combined with subnitrate of bismuth in large doses, with wine of opium or deodorized tincture.

The greater or less usefulness of calomel in cholera, as attested by experience in so many epidemics, beginning in 1885, may be ascribed to its antiseptic qualities, although it is probably as efficient in controlling vomiting as any other drug. The plan pursued at the New Hamburg Hospital and at the Moabit Hospital in Berlin was to give an initial dose of four to seven grains (0.3 to 0.5 gm.), after which 1-3 to 3-4 grain (0.02 to 0.05 gm.) was given every two hours through the first and second stages. A portion of the calomel becomes changed in the intestine to corrosive sublimate; and as corrosive-sublimate solutions have a fungus-destroying action, in a strength of 1 to 30,000, it is reasonable to suppose that the bacilli in the intestine are directly killed by the calomel.

II.—The indications in the *second stage* are to relieve the painful cramp, to continue to try to check the discharges, and to compensate for the loss of liquid by the vomiting and purging.

For the relief of cramps morphin hypodermically is to be preferred, because of the promptness of its effect and because absorption from the gastro-intestinal mucous membrane is much hindered, if not altogether prevented, in true cholera, while the vomiting is a further obstacle to the administration of medicine by the mouth. Full doses should be given, 1-6 to 1-4 grain (0.01 to 0.016 gm.), which may be repeated, if necessary. If circumstances compel the administration of anodynes by the mouth, chlorodyne is one of the best, and is well administered in brandy or whisky.

Such administration, too, fulfills any indication for opium to control the bowels. Some difference of opinion exists as to the propriety of checking the discharges in this stage, the chief reason assigned being that the bacilli, whose presence is directly or indirectly the cause of the flux, are thus retained. But such objection is offset by the fact that the flux itself is the greater source of danger and that, if it can be controlled, the bacilli in the bowel are comparatively harmless. Unfortunately, in the later stages, when the flux is established, nothing avails to control it, and the opiate may as well be limited to that hypodermically administered for the relief of pain. I quite agree with those who hold that, notwithstanding the opposition to it, opium will retain its place among the chief weapons against the disease.

The effect of the copious discharge is to produce the intense exhaustion referred to under symptomatology, and it is imperative to counteract this, if possible, by stimulants freely administered. Champagne, brandy, and ammonia, combined with ice and carbonated waters, are suitable. If not retained by the stomach, whisky, ether, and the aromatic spirit of ammonia may be given hypodermically in thirty-minim (2 gm.) doses frequently repeated. The hope of benefit from these remedies is justified, if reaction once sets in.

More serious still is the drainage of liquid from the tissues, and the most serious consequences ensue from the resulting stagnation in the blood. To restore its liquidity is, therefore, of the greatest importance. Transfusion of watery solutions suggests itself, but the difficulty and delay involved in practicing are opposed to its use. Hypodermic injections of hot saline

Fig 12.—1. Rubber reservoir and tube of fountain syringe for hypodermoclysis. 2. Attachment for cannula. 3. Soft rubber rectal tube. 4. Needle. 5. Cannula.

solutions or hypodermoclysis, also enemas or enteroclysis of similar fluids, slightly astringent, were practiced successfully by Cantani in Italy in 1892, and have been continued with various results in Europe, and in a more limited manner, with satisfactory results, at Swinburne Island in New York Harbor. The method practiced at the latter place, as described by Judson Daland, is as follows: Water at 40° C. (104° F.) previously sterilized, and containing 0.8 per cent. of sodium chlorid and one per cent. of brandy, was

introduced under the skin in the midaxillary line in the region of the floating ribs, through a long hypodermic needle and cannula attached to the tube of a fountain syringe or Davidson syringe. The former is preferred, because the pressure may be neatly regulated by raising or lowering the bag. One or two quarts may be introduced, thirty to forty-five minutes being required, in favorable cases for the former quantity. When absorption is slow, it may be facilitated by manual manipulation at the seat of the swelling that results at the point of injection. In unfavorable cases a much longer time is required to introduce this quantity, as much as four hours, whence the rate of absorption becomes of prognostic value. The operation may be repeated in two hours, or in severe cases one quart may be injected in each flank, repeated as soon as absorption is complete. The quantities to be used may be laid down at, for an adult, two pints (1 liter); an adolescent, one pint (0.5 liter); and an infant, 1-2 pint (0.250 liter). Other sites may be selected for injection, as the buttocks, inner surface of the thighs, or below the pectoral muscle. The neighborhood of the neck should be avoided because of the possible edema of the larynx, such an accident having occurred at Swinburne Island. The benefit derived from the use of this measure under other circumstances,—as, for example, succeeding large hemorrhages and uremia,—together with the facility with which it can be carried out, commend it strongly. *A heaping teaspoonful of common salt to a quart of sterilized water furnishes with sufficient nearness the proportion desired.*

Whenever the discharges have been so copious as to make it reasonable that the vessels are becoming drained, hypodermoclysis is indicated, and may be repeated every two, four, or six hours as required.

Enteroclysis is made with a one or two per cent. solution of *tannic acid* at a temperature of 45° C. (113° F.). For an adult 2 quarts (2 liters) may be administered; for an adolescent, 1 quart (1 liter). It is introduced slowly, by a fountain syringe or Davidson syringe, through a rectal tube with lateral outlets but closed at the end. The tube is introduced gently by a combined rotary and pushing motion to the depth of 10 inches, when the fluid is allowed to enter slowly, consuming not less than ten minutes. The patient should, of course, be encouraged to retain the fluid, and may be aided by pressure on the anus with a napkin. Enteroclysis is said to be useful in any moderately severe case of cholera, and may be given night and morning, more frequently in severe cases. According to Daland, experiments made at Swinburne Island in the autumn of 1892 showed conclusively that when thus introduced fluid can be made to pass through the ileocecal valve into the small intestine. In fact, several patients vomited the solution.

It is in the algid stage that this treatment is more particularly used, but other means must be taken to keep up the warmth of the body. To this end the patient is immersed in the hot bath at a temperature of 38° to 42° C. (100° to 107° F.). In favorable response the warmth of the body returns, the pulse is fuller and stronger, the respiration deeper. Hot-water bottles, hot-water bags, and hot bricks may be applied alongside the body.

III.—In the *third stage*, that of reaction, indicated by the return of warmth, pulse, and heart-beat, and especially the establishment of the urinary secretion, restorative measures are continued with the addition of judicious nutriment, preferably in the shape of peptonized foods, especially peptonized milk. Great care must be exercised lest diarrhea be induced by too liberal feeding. Convalescence is necessarily very slow in serious cases, and relapses are prone to occur.

APPENDIX.—THE EXAMINATION FOR CHOLERA BACILLUS.

I add the method practiced for this purpose in the Bacteriological Institute at Berlin furnished by Dr. Louis Fischer.

The articles necessary are:

1. A microscope with Abbé's condenser and an oil-immersion lens of 1-12 inch focal distance.
2. A solution of fuchsin 1 gm. in 90 c. c. distilled water and 10 c. c. alcohol.
3. A few pipettes, glass rods, cover-glasses, and slides.
4. A few platinum wires melted or soldered to the ends of glass rods.
5. A few "hollow" slides.
6. Ten to 12 glass plates or glass panes, about 12 cm. long and 9 cm. wide.
7. About a dozen ordinary flat plates.
8. An alcohol lamp or gas, preferably a Bunsen burner.
9. A number of test-tubes with sterilized gelatin.
10. A number of test-tubes with sterilized nutrient bouillon.
11. A few Erleymer's glasses, about one-third filled with 1 per cent. peptone solution—1 gm. peptone, 0.5 gm. chlorid of sodium, 100 gm. distilled water.
12. Concentrated sulphuric acid.

The dejecta of the suspected patient are scattered in as thin a film as possible on a glass plate, and this is carefully examined by the aid of a platinum wire for a mucous flake ("Schleimflocke"), which is laid on the edge of the plate and isolated. From this is taken a piece the size of a pinhead by means of a platinum loop sterilized by drawing it through a Bunsen burner. The fragment is rubbed on a cover-glass until it is evenly divided; superfluous material is removed by pressing another cover-glass over it; the two are separated, and allowed to air-dry.

The glass cover is then drawn three times through the flame of the Bunsen burner in the same manner as for the examination of sputum for tubercle bacilli, and by means of a pipette a few drops of fuchsin solution are placed on it, allowed to remain one or two minutes, and then washed off in distilled water. A drop of water is put on the cover-glass, which is laid on a slide and examined with the oil-immersion system. If it be desired to preserve the specimen, after staining with fuchsin solution wash off the excess of stain with distilled water, allow it to get thoroughly air-dry, add Canada balsam, and mount.

In some of the fulminating cases where the intestinal contents are colorless or have a pale-red color, with slimy flakes or with a flour-soup mass, especially in the period of reaction, the cases running a slow course, no mucous flakes will be found, but large quantities of blood. Here may be found, besides cholera bacilli, numerous other micro-organisms, while the cholera bacilli are but sparingly present. To render a diagnosis absolutely positive in such cases, "cultures" are necessary.

Cultures can be made in "hollow slides" by smearing the border with vaselin, then bringing a small drop of sterilized bouillon into this hollow groove of the slide by means of a platinum-wire loop, and inoculating the bouillon with the smallest possible particle of the suspected mucous flake. The cover-glass is carefully laid on the vaselin, which serves to render the groove air-tight, and also prevents evaporation of the drop of sterilized

bouillon. The slide is then laid aside at a temperature of 20° to 22° C. (68° to 70° F.). The room can be heated, if the temperature is below this. In about twenty-four hours the bouillon becomes turbid, and the slide can be examined with the oil-immersion lens without disturbing the culture. The best place to examine is the border line, and even if but few cholera bacilli were originally present, they grow so rapidly that they can be easily recognized by their curved shape.

Culture Method by Schottelius.—Take 100 to 200 c. c. of the suspected dejecta from the intestinal contents and place them in a beaker glass containing 250 to 500 c. c. of mild alkaline meat-bouillon, and mix thoroughly; then let this mass stand twelve to twenty-four hours at a temperature of 30° to 40° C. (86° to 104° F.). After this time the cholera bacilli have usually increased in numbers, and are found on the upper layer of the fluid. Introduce at the upper layer a platinum loop, take out a small drop the size of a lentil seed, rub it on a cover, and allow it to dry thoroughly in the air; then stain, as previously described, with the fuchsin solution.

Postmortem Tests.—To examine suspected intestinal contents, open the abdominal cavity carefully and ligate at two places with stout twine a piece of the ileum well filled with fecal contents, about three to four centimeters in length, and taken from near the cecum. A double ligature should be applied at each end and the cut made between the two, so that the intestinal contents will not be spilled in the abdominal cavity. It is well also to cut out a piece of the intestine three to four centimeters in length from the upper portion of the ileum, and to lay the excised portions in ordinary water until ready for examination. The method is the same as has been described—that is, take a small piece of flocculent mucus the size of a pinhead, etc.

Gelatin stroke and stick cultures, and also potato cultures, can be made for examination. The spirilla also grow on blood-serum and agar.

Cholera bacilli require for their growth a mild alkaline nutrient medium, and are very quickly destroyed by mineral acids. They do not develop readily in ordinary water, owing to the presence of other bacteria, which destroy them; they do develop, however, very rapidly in sterilized water.

DYSENTERY.

SYNONYM.—*Bloody flux.*

Definition.—The term dysentery, derived from the Greek words for difficult and bowel, is applied to inflammations of the large and sometimes, although to a less extent, of the small bowel. The condition can be best considered under three heads which represent varieties or different forms of the disease. These are: 1st, catarrhal, 2d, bacillary, and 3d, amœbic dysentery.

CATARRHAL DYSENTERY.

Definition.—Catarrhal dysentery is the simplest and most common form of the disease met with in temperate climates. It is characterized by an increased mucous secretion associated with desquamation of the epithelium covering the gut, together with a variable involvement of the solitary lymphatic nodules of the large intestine and of both the solitary and agminated nodules of the small intestine.

Etiology.—This form occurs more frequently as an accompaniment of other diseases of adults than as a simple uncomplicated process. It attends the specific intestinal lesions in typhoid fever and tuberculosis and is commonly associated with the acute infectious exanthemata and not infrequently with diphtheria. It is the form of dysentery caused by simple irritants, of which unripe and indigestible food forms a liberal source. In children, especially during the hot summer months, but to a certain extent throughout the entire year, this form is met with. As in adults, it may be the result of the ingestion of indigestible food or other irritants, but in young and nursing children it forms a part of the so-called entero-colitis of the summer months. In the better characterized entero-colitis of children Duval and Bassett have obtained the bacillus of Shiga from the dejections and from the mucous membrane of the intestines in fatal cases.

Morbid Anatomy.—Changes in the affected intestine are of different grades. In the lighter forms there is merely an excessive secretion of mucus associated with desquamation of the epithelial cells, exudation of more or less serum, and the emigration of a small number of leukocytes. The mucosa is swollen and congested. In severer forms the surface of the gut is covered with mucus, streaked with blood. The mucosa is much injected, bleeding points or ecchymoses can be made out, and the lymphoid nodules are enlarged and prominent. Not infrequently small defects in the mucosa exist in connection with the nodules, constituting small ulcers. The latter rarely extend beyond the limits of the nodules, and pseudo-membrane never occurs in connection with them.

Symptoms.—Catarrhal dysentery is usually ushered in by *diarrhea*, the first stools being copious and painless. Soon, however, these are replaced by small mucous discharges streaked with blood and accompanied by crampy abdominal pains, technically known as *tormina* (twisting pains) and straining or *tencsmus*. The latter is exceedingly trying, causing a constant feeling of unsatisfied desire for stool, so that the patient is disposed to sit constantly on the closet or to go back repeatedly many times in a single hour, experiencing at the same time intense burning pain at the anus. Yet the total quantity discharged in the twenty-four hours is not large. From 28 to 42 ounces are a full amount.

Sometimes a *chill* is the initial symptom. The *tongue* is furred and at first moist; later it may become dry. There may be *nausea* and *vomiting*.

There is always more or less *fever*, sometimes very slight, at others decided, the temperature seldom exceeding 103° F. (39.4° C.). There are the thirst and acceleration of pulse usually attending fever, and sometimes the former is extreme. The *abdomen* may be tender, but not necessarily so. It may be tumid or flat and hard. In addition to the characteristic features of the stools already mentioned, scybala or hard fecal masses may be present at first. Later the stools are frequently green in color, from the presence of bile—*bilious dysentery*—and increase in their transit the burning feeling already mentioned. In addition to blood-corpuscles and leukocytes the microscope recognizes large round and oval epithelioid cells containing fat-drops and vacuoles; also at times the *cercomonas intestinalis*. Until recently no specific organisms were found in the simple catarrhal form of dysentery. F. C. Curtis has found the *bacillus pyocyaneus* in an epidemic of dysentery at Harlwick, N. Y.

The milder cases of catarrhal dysentery are self-limiting, terminating usually in a week, when the character of the stool changes. Other cases

are more intractable and resist even judicious treatment for a long time, becoming even chronic.

Diagnosis.—The diagnosis of acute catarrhal dysentery is very easy. The tormina and tenesmus with the frequent blood-stained mucous stools occur in no other affection. Malignant disease of the rectum is sometimes mistaken for chronic dysentery. Examination of the rectum should be made in all prolonged cases.

Prognosis.—The prognosis is generally favorable. As intimated, many mild cases get well without treatment, and when judiciously handled unfavorable termination is rare. Favorable termination is not, however, invariable, and cases sometimes end unfavorably after a prolonged course, or they become permanently chronic and incurable. Emaciation and exhaustion are rapid, and even a mild attack rapidly reduces the strength of its victim.

BACILLARY DYSENTERY.

Definition.—The form of dysentery most commonly present in temperate and tropical regions, appearing in a variety of forms. Under it are to be included: First, pseudo-membranous, croupous, or diphtheritic. Second, ulcerative. Third, chronic dysentery.

Etiology.—The lower part of the large intestine is most frequently the site of the lesion, but the entire large and more rarely the small gut may be affected. The difference between the acute, pseudo-membranous, and chronic forms are striking, notwithstanding which, the evidence at hand tends to connect them to one causative factor. Beginning with the researches of Shiga in Japan, in 1898, which were followed by the investigations of Flexner and Barker carried out in Manila, in 1900, and afterwards by Flexner in this country, and Kruse and others in Germany, the evidence has grown in favor of the *B. dysenteriae* (Shiga) as being the specific cause of this variety of dysentery.

The *Bacillus dysenteriae* is a well-characterized micro-organism belonging to the colon typhoid group of bacilli, which can be distinguished by its cutural and other characteristics. In morphology it differs only slightly from the typhoid bacillus, with which it has certain cultural properties in common. It grows upon ordinary culture media readily, and brings about little change in milk excepting to cause a slight alkalinity. It is slightly motile when first isolated, but quickly loses its motility on artificial cultures, but this can be restored by passage through experimental animals. Flagella surrounding the body of the bacillus have been demonstrated by Vedder and Duval, of the University of Pennsylvania. The organism is pathogenic for a wide series of laboratory animals, and when injected into the intestine of cats, or fed to them after alkalization of the gastric juice, it is capable of setting up an inflammation of the gut from which the bacillus may be recovered. Taken into the stomach of man it rapidly sets up a severe colitis. There are two instances on record of its action on man: The first, reported by Flexner, in which a small quantity of a culture was accidentally aspirated into the mouth by one of his assistants, the intestinal symptoms appearing within forty-eight hours: the second, reported by Strong, in which a Filipino prisoner voluntarily swallowed a portion of a culture of the bacillus, in which case the symptoms quickly developed and were of marked severity, the bacillus being recovered from the stools. The man finally recovered.

Bacteriological Diagnosis.—Diagnosis of this form of dysentery can be established in two ways: First, by recovery of the specific organism from the stools; second, by obtaining the agglutination reaction with the blood of the patient and the specific bacilli in a manner similar to that of the Widal test in typhoid fever.

In the acute disease the specific bacilli are abundant, and can be separated without great difficulty from the dejecta. For this purpose solid contents are avoided and mucus or blood-stained mucus is selected for examination. Plate cultures upon agar-agar are made and incubated for twenty-four hours. The colonies which have developed at the end of this period are not chosen for further study, but are carefully marked with a blue wax pencil and the plates returned to the incubator for another twenty-four hours. The second crop of colonies usually contains a large proportion of the dysentery organisms, which grow more slowly than the colon bacillus in the mixtures of the two organisms. Transplantations from the second crop of colonies are made into glucose agar tubes, which are incubated for a day and all gas-forming colonies excluded as being non-dysenteric. The tubes which show no gas are then further examined, and among them the specific organism will be found. (Duval.)

The agglutination test with the blood of persons ill of bacillary dysentery is easily obtained. For this purpose cultures, twenty-four hours old, upon agar-agar, are employed, from which suspensions are made in bouillon. In using the blood, it is preferable to employ the wet method by which the blood is obtained in capillary tubes, from which the serum can be collected. After proper dilution of the serum the tests are carried out in the usual manner. Positive reactions may be obtained in dilutions varying from 1-20 to 1-1000 in a period of from one-half to one hour, and as early as from the third to the fourth day of illness. This method is applicable to the study of all cases of dysentery, as well as the entero-colitides of children.

Morbid Anatomy.—The anatomical features of bacillary dysentery vary with the form and duration of the disease. The most acute cases are those running a rapidly fatal course and involving the entire large gut and a variable length of the lower small intestine. The mucous membrane is greatly swollen, suffused with serum and blood, presenting a pulpy appearance, but without visible false membrane. These are the forms which result fatally in 48-72 hours, and which are met with in tropical countries, and sometimes in institutional and other epidemics in temperate climates. The usual form of bacillary dysentery is the pseudo-membranous. In this the extent of the lesion varies, sometimes appearing in the rectum and sigmoid flexure, and sometimes extending throughout the large gut. The membrane, which is grayish-white in color, presents a granular surface, and appears first upon the elevations of the mucosa corresponding to the insertion of the bands of longitudinal muscle and the transverse lines of the colic pouches. As the condition progresses in severity the intervening mucosa is covered with pseudo-membrane. The entire mucosa is injected, swollen, and covered with blood-stained mucus, beneath which bleeding points may be discerned. Upon microscopical examination the pseudo-membrane is found to consist of a fibrinous and cellular exudation which lies upon the surface and penetrates into the substance, for a variable distance, of the mucosa. The glands of Liberkuhn undergo necrosis and become invaded by pseudo-membrane. Large numbers of micro-organisms

are present in the dead tissue, and the blood-vessels of the mucosa are extensively occluded by thrombi.

A demarcating inflammation takes place at the limits of the living and necrotic tissue, causing separation of the latter, which upon exfoliation leaves behind defects which constitute the acute dysenteric ulcers. The disease may come to an end at this stage or an earlier one, and the integrity of the mucosa be restored, or the necrosis may extend more deeply and involve the depth of the mucosa and be associated with marked inflammatory changes in the submucous and muscular tunics. In these instances ulceration may extend through the mucosa and invade the submucosa, and even penetrate more deeply, and in the subsequent process of repair new tissue develops in the submucosa which leads to the permanent thickening of the intestinal wall. It is this form of dysentery which tends to pass into the chronic disease, in which ulceration is deep and persistent, and much new tissue develops in the submucosa, in the mucosa, and even in the muscular coat. Owing to the persistence of the ulceration and possibly to the interaction of secondary micro-organisms, including the pyogenic cocci, always present in the intestinal canal of man, the ulceration extends not only more deeply, but tends also to heal slowly and imperfectly, whence arise the symptoms characterizing chronic ulcerative dysentery. That the specific organism persists throughout long periods, where these pathological conditions are present, is shown by the acute exacerbations of the disease and by the association of the chronic ulcerative with fresh pseudomembranous inflammation met with not infrequently at autopsy. It is during the exacerbation that the specific bacillus is to be sought in the dejecta and the blood reaction looked for. Among the consequences of the tissue production in chronic dysentery, polypoid outgrowths are met with. These consist of portions of the mucosa and submucosa, in which an overplus of new tissue is developed, and which come to project into the lumen of the gut. Partially through the action of gravity and through other causes they tend to lengthen, whence they come to be attached by narrow pedicles to the wall of the gut. Depressed scars, over which the mucosa is atrophied, also mark the site of healed ulcerations.

The new formation of connective tissue throughout the coats of the gut may be so extensive as to bring about, after its contracture, serious deformation and narrowing of the lumen. Inflammation sometimes extends to the peritoneal coat, whence adhesions to the neighboring parts take place. Only rarely does ulceration proceed so rapidly, or fail to be attended by connective tissue formation, as to perforate the peritoneal coat.

Symptoms.—The symptoms of bacillary dysentery are those of the simple catarrhal form greatly intensified. The *fever* is higher, the *pain* is greater, the *tormina* and *tenesmus* are more severe, the *stools* are more bloody, and the *adynamia* is more profound. *Delirium* is often present, and the tongue may be dry. The abdomen is tender and swollen, and typhoid fever may be simulated. The symptoms in the secondary form are less severe than in the primary.

Complications and Sequelæ.—The complications in this form of dysentery are more numerous. *Abscess of the liver* is one of them, and is ascribed to thrombotic extension from the seat of inflammation along the vessels of the portal system into the liver, or to emboli carried from the primary focus to the liver. *Perforation* of the bowel is not a very rare complication, having been found by Woodward, in a study of the statistics of

the late Civil War in America, 11 times in 108 autopsies. This accident is followed by a peritonitis, which is usually fatal, the local symptoms of which vary with its exact seat. If in the neighborhood of the cecum, perityphlitis ensues; if lower down in the rectum, a proctitis. A peritonitis may also arise by extension of the inflammation from the mucous lining of the bowel.

The same opportunities enabled Woodward to show the undoubted association of *malaria* with dysentery, though it is likely that the "chills" referred to in older reports were sometimes septic and due to the dysentery. The same is true of the *joint swelling* described by the older authors, among whom was Sydenham. They may be a part of pyemic processes. *Paralysis*, commonly paraplegia, as a sequel, is attested by Woodward and Weir Mitchell. Pleurisy, pericarditis, endocarditis, and Bright's disease are among sequelæ reported.

Diagnosis.—The same diagnostic symptoms that enable us to recognize the other varieties of dysentery attend this in severe degree, but it is the occurrence of successive cases that gives the stamp by which we recognize the diphtheritic type. (See also bacteriological diagnosis, page 107.)

Prognosis.—The prognosis of this form of dysentery is the most unfavorable of all the varieties. Most cases perish, death being preceded by extreme adynamia and other symptoms of the typhoid state, including dry tongue, stupor, emaciation, and the cadaveric countenance. Consciousness is sometimes painfully persistent to the end.

AMŒBIC DYSENTERY.

SYNONYMS.—*Amœbic Enteritis; Tropical Dysentery.*

Definition.—An ulcerative inflammation of the large intestine due to *amœba coli*. This form has sometimes, incorrectly, been termed tropical dysentery. It occurs in the tropics, but also in temperate regions, while the commonest form of the disease in the tropics would appear to be bacillary dysentery.

Etiology.—The studies of Kartulis in Egypt, of Councilman and Lafleur in America, and Kruse and Pansini in Italy, have established amœba coli as the cause of this variety of dysentery. The organism was, however, first described by Lambl in 1859, and later by Lösch, but its relation to tropical dysentery was first clearly established by Kartulis. The amœbæ are found in the dejecta, in the intestinal ulcers, and in secondary liver abscesses of the disease. The organism varies from 15 to 20 microns in diameter and is actively motile when examined in the living state. It consists of two portions, an outer ectosarc and an inner endosarc. Its movements are brought about through the propulsion of the former, after which the granular inner substance flows into the pseudopodia. The amœba is phagocytic, taking up foreign substances from the intestine, etc., and especially englobing the red corpuscles. At present two varieties of amœbæ are distinguished as occurring in the stools: the first non-pathogenic—*amœba coli mitis*—and the second pathogenic—*amœba coli*. The former has been found repeatedly in healthy stools, and it does not exhibit phagocytic properties for red corpuscles. In this country amœbic dysentery has been found to occur as a sporadic disease, especially in the Southern States, but also in Pennsylvania, New York, and the New England States.

Morbid Anatomy.—The intestinal lesions are usually limited to the

large intestine; rarely they are found in the ileum. The characteristic lesion is ulceration, involving the mucosa and submucosa. In early ulcers a small defect only is found in the mucosa; more rarely the muscular coat is invaded, and rarest of all, the peritoneal coat. In the course of the ulceration the submucosa becomes infiltrated with a grayish, gelatinous material, the exfoliation of which gives rise to the ulcer. In this material there are few preserved cells, but it consists chiefly of necrotic material, in which only a few pus cells can be made out. Amœbæ may be discovered in the necrotic tissue, as well as in the adjacent portions of the mucosa and submucosa. In the immediate neighborhood of the ulcer proliferation of the connective tissue takes place which, in favorable cases, may completely restore the defect, and in chronic cases brings about permanent changes in the gut similar to those described in chronic bacillary dysentery. Pseudo-membrane is never present in uncomplicated cases, but instances of combined amœbic and bacillary dysentery, in which pseudo-membrane has been present, have been described.

Microscopical Diagnosis.—Detection of the specific amœbæ in the stools, or of secondary liver abscesses, confirms the diagnosis of the disease. Great care should be exercised to obtain fresh material for microscopical examination, and bits of mucus, rather than fecal material, should be chosen for study. The mucus or pus is slightly pressed out, but not too firmly, under a cover-glass, and the slide slightly, but carefully, warmed up to body heat, before examination. Inasmuch as desquamated epithelial cells sometimes take on a round form and simulate amœbæ, it is desirable that a definite movement be detected before passing upon the nature of the suspected cells. Living amœbæ, especially those enclosing red corpuscles, are taken to indicate the nature of the pathological condition of the intestine.

Symptoms.—The symptoms of amœbic dysentery are similar to those of catarrhal dysentery, but much more irregular and prolonged. The onset is usually less sudden, but may be equally so. The stools are less numerous, and are apt to be more liquid and more copious. They abound in the amœbæ coli. The straining at stool is less severe and persistent, while there may be several days of relief, to be followed by the usual train of symptoms. The fever may be severe or mild.

Complications.—The most common and serious complication is *abscess of the liver*, which is now believed to be due to the wandering amœba dysenterica, which reaches the liver through the blood-vessels. The abscess may be single or multiple. In the former case it may be of large size, involving fully half of the bulk of the liver. The multiple abscesses are smaller in size and superficial. The abscess walls are peculiar, being ragged from the presence of necrotic projections. Only occasionally, in the older abscesses, are there firm, smooth, fibrous walls. Next to the *innermost necrotic zone* is a zone of *cellular infiltration* encroaching upon and destroying the liver-cells, and external to this again a zone of *intense hyperemia*. The contents of the abscess are not pure pus. In fact, the paucity of the pus-cells here is as significant as in the inflammatory infiltration of the mucosa, indicating a similarity in the etiology. The pyoid material consists rather of fatty and granular débris and the amœbæ, which are also found in the walls of the abscess. These abscesses sometimes break into the lungs, carrying the amœbæ with them, which are sometimes, under these circumstances, found in the expectoration.

In addition to the abscesses described there are found also in the liver

in amœbic dysentery patches of *circumscribed necrosis*, scattered through the liver as the result of the action of the amœbæ.

Diagnosis.—The diagnosis is rendered easy by the recognition of the *amœba coli* in the stools, which should be examined by the microscope in every case of dysentery as directed under microscopical diagnosis.

Prognosis.—The prognosis is much more serious than that in the catarrhal variety. The course of the disease is always prolonged, and a fatal issue is much more frequent. It would seem that the patient must outlive the organism before he can recover, and even then recovery is delayed by the exhausted condition into which he has fallen in the struggle with his microscopic guest. When the termination is most favorable, cases of amœbic dysentery last from six to twelve weeks.

Treatment of Dysentery.—The first measure of treatment of *catarrhal dysentery* duly recognized should always be a purgative. No aperient is better than castor oil. An ounce of oil (30 c. c.), guarded by 10 to 20 drops (0.66 to 1.33 gm.) of laudanum, is the proper dose for an adult. The saline treatment, especially when there is high fever and no marked adynamia, is also efficient, working a rapid cure in many cases. Two drams (8 gm.) of sulphate of magnesium, or 1-2 ounce (16 gm.) of Rochelle salts dissolved in water, should be given every hour until copious watery purgation results.*

When this end is obtained by either remedy, an opiate may be given. Plain opium in doses of one grain (0.066 gm.) every three hours, or 1-2 grain (0.033 gm.) of the extract, is the favorite. Or the drug may be combined with bismuth subnitrate in ten-grain (0.66 gm.) doses, or with one of the astringents, tannic acid in two- to five-grain (0.132 to 0.33 gm.) doses, or the acetate of lead, one- to two-grain (0.066 to 0.132 gm.); or with salol. Very comforting in quieting rectal irritation is an opium suppository containing one grain to two grains (0.066 gm. to 0.132 gm.) of opium, or 1-2 grain to a grain (0.033 gm. to 0.066 gm.) of the extract.

Hope's camphor mixture is an old remedy which sometimes acts well, especially in cases disposed to become chronic. Dr. Hope's formula, originally suggested in 1826, is as follows:

℞ Acidi nitrosi, f ʒj (4 c. c.)
 Mist. camphoræ, f ʒ viij (240 c. c.)
 M. et adde tr. opii, gtt. xl (1.2 c. c.)
 Sig.—A fourth part to be taken every three or four hours.

The Hope's camphor mixture of the shops; made with nitric acid instead of nitrous acid, should not be substituted.

It goes without saying that the food should be liquid and of the blandest kind: boiled milk, better still peptonized, light animal broths, and beef-juice, not beef-teas, are the type. Barley or rice may be added to such broths, and should be thoroughly cooked.

The first consideration in the treatment of *bacillary dysentery* is a *bland and non-irritating, but nourishing, diet*, one that leaves as little residue as possible. The peptonized foods, such as peptonized milk and beef-pepto-

*The following striking results would seem to justify the saline treatment: Day treated 60 cases of dysentery, 25 of which received ipecacuanha and opium; the remaining 35 were treated with magnesium sulphate. Under the former method of treatment the death-rate was 22 per cent. and under the latter 2.9 per cent. The recoveries occurring under the former treatment were slow and accompanied by frequent relapses; under the latter they were complete and rapid, but it was always found advisable to continue one-dram doses of magnesium sulphate three times daily for a couple of days after the stools had ceased to be dysenteric.

noids, in addition to beef-juice and somatose, are the types. To these, stimulants should be freely added. *Opiates* are needed to relieve the pain, and their hypodermic use is sometimes especially efficient for this purpose. When the necrotic membrane is removed, an extensive ulcerated surface remains to be healed. Such healing is favored by the restrained peristalsis that opium produces. The same purpose may be served by the use of ipecacuanha, if the effect claimed for it by the East Indian physicians is produced. Directions for its administration are given below.

On the other hand, it is doubtful whether soluble remedies intended for the direct healing of the ulcers ever reach these surfaces in an active state, when administered by the mouth. Nitrate of silver, when administered, does sometimes, however, reach the lower bowel. Bismuth, being largely insoluble when administered in large doses, undoubtedly reaches the bowel, and may produce some healing effect. More promising is the use of iodoform, which may be also expected to reach the part affected, and which is not only more healing in its action, but is also antiseptic. It may be given in a pill or capsule, in doses of 1-2 grain to 3 grains (0.0324 to 0.194 gm.).

The same indication as to *diet* exists in the *amæbic* as in the other forms of dysentery. It is apparently in this form, of which only isolated cases are met in temperate climates, that the *ipecacuanha* treatment of the East Indian physicians has been so successful. It is claimed to act as a muscular sedative and secretory stimulant; by its effect the former allays the exaggerated peristaltic activity so characteristic of the disease, by the latter it augments the secretion of mucus as well as stimulates the activity of the liver-cells in bile formation—a function which in dysentery is in abeyance. Great stress is laid on the mode of administration. A preliminary dose of laudanum is given, and in half an hour afterward from 20 to 60 grains (1.332 to 4 gm.) of ipecacuanha. For three hours after the first dose only a little ice should be sucked, and after that a little iced soda-water and milk administered. Beef-tea or bread or light foods are fatal to the favorable action of ipecacuanha, and to the use of such foods failures are ascribed by the advocates of the treatment. On the second day the drug is administered in reduced quantity, supplemented by salicylate of bismuth, quinin, naphthol, and opium, while milk should form the staple food. Later, farinaceous foods and soups may be carefully given, but no solids should be permitted for a long time.

Warm injections of quinin, 1 to 5000, 1 to 2500, and 1 to 1000, have been employed at the Johns Hopkins Hospital with good results, the amœbæ being rapidly destroyed by them. Perhaps ipecacuanha acts similarly. For the relief of pain opiates must also be administered, preferably by the rectum in suppository or small starch-water enemas; or morphin may be given hypodermically if the stomach be sensitive.

Serum Therapy.—The immunizing protective effect of vaccines against the dysentery bacillus and the protective and curative effect of antidysenteric sera demand allusion. Their availability has received fresh support from recent experimental studies by Simon Flexner and Frederick P. Gay.*

Dysentery vaccines were made of dead cultures as described in Gay's paper. Guinea pigs which received one or more subcutaneous injections of subminimal lethal doses showed a marked protection against multiple

* "Vaccination and Serum Therapy against the Bacillus of Dysentery. An Experimental Study." By Frederick P. Gay, "University of Pennsylvania Medical Bulletin," November, 1902.

intraperitoneal lethal doses of the living organism. It is interesting to note that while protection afforded by a given vaccine against its own strain of bacillus dysenteriae was absolute within limits, it was found that under similar condition such protection may not be secured against other strains, suggesting the advisability of combining several strains of bacilli after their cultivation in the preparation of vaccines.

Antidysenteric serum was obtained from the horse after immunization. It was found to possess agglutinative properties for bacillus dysenteriae. This serum also had protective and curative properties against multiple fatal intraperitoneal doses in guinea pigs. Gay concludes that this protective power may be regarded as proven beyond peradventure.

The effect of antidysenteric sera in the cure of dysentery in the human being is as yet limited to the serum treatment of Japanese dysentery, as reported by Shiga. Of 250 cases thus treated the mortality averaged 10 per cent. as against 36 per cent. in cases treated by ordinary methods.

CHRONIC DYSENTERY.

Any one of the forms of dysentery described may become chronic, but bacillary dysentery is the more usual form.

Morbid Anatomy.—All the lesions described as occurring in the different varieties of dysentery may be present. The most common is ulceration, which is variously extensive and exhibits also efforts at healing. On the other hand, cases of chronic dysentery are met with in which there are no ulcers whatever. The coats of the bowel are thickened, especially the submucosa and the muscularis, while patches of black and slate-gray discoloration are scattered through it, the result of blood extravasation and disintegration. Puckering, pseudopolyposis, and cystic degeneration may be present as described under Morbid Anatomy of bacillary dysentery.

Treatment.—The patient should be put to bed on a *diet* easy of assimilation and furnishing a minimum of waste. Its quantity should be just what is needed and no more. From what has been said it may be inferred that I have little confidence in methods of treatment the object of which is to get remedies to the diseased bowel by way of the mouth. *Bismuth* in large doses, *iodoform*, and even *nitrate of silver* may, however, be tried for the purpose. One-half to 1 dram (2 to 4 gm.) of bismuth should be given at a dose, so that from 12 to 15 drams are administered in the course of a day. Iodoform may be given as above directed.

The *topical treatment* of chronic dysentery by way of the rectum is that on which most reliance is placed at the present day. Its object is to get remedies to the diseased part. To this end they are dissolved and their solutions are introduced into the lower bowel. *Nitrate of silver* is the favorite remedy, but alum, sulphate of zinc, sulphate of copper, and acetate of lead are also used in the same doses. Twenty to 30 grains (1.3 to 2 gm.) are dissolved in a pint (1-2 liter) of water, and from 3 to 6 pints (1.5 to 3 liters) are injected at one time through a long tube gently introduced well up into the bowel, but at the onset weaker solutions and smaller quantities are injected. The patient should be placed on his back with the hips elevated by a pillow, so that there may be the coöperation of gravity. I have had many opportunities to use this treatment in the wards of the Hospital of the University of Pennsylvania, and confess to disappointment in the

results. My cases improved to a certain point, but none got well. The treatment is sometimes painful.

Very decided counterirritation to the abdomen, by iodine and even by blisters, is sometimes of decided advantage. At least these measures seem to mark the turning point in the disease.

THE PLAGUE.*

SYNONYMS.—*The Bubonic Plague; Oriental Plague; Black Death; Black Plague; Pestis Hominis.*

Definition.—The plague is a febrile infectious disease, characterized by a tendency to buboes or carbuncles, in addition to the usual phenomena of the typhoid state.

Historical.—It has already been said that the historical plague of Athens, described by Thucydides, corresponded rather with the typhus of to-day than with the Oriental plague, which still occurs in Asia, and of which a grave epidemic is now (1903) raging in the East Indies and China, the last previous epidemic having occurred in Hong-Kong, China, in May, 1894, from which 2500 died in three months. The plague of the sixth century, Justinian era, the Justinian Plague, is believed to be the bubonic plague of to-day, as was also "the black death" of the fourteenth century, in which perished a fourth of the population, and the plague of London in 1665, which destroyed 70,000. With the improvement of hygienic conditions it has been growing rarer, until the last outbreak occurred, which has practically prevailed since September, 1896, with certain abatements and exacerbations. From that date to January 13, 1899, in the Bombay Presidency, 214,197 had the disease, and 169,240 died. This epidemic has spread to Japan, Honolulu, and to Portugal. A few cases also occurred in San Francisco, U. S. A., in the first half of 1900. According to J. F. Payne, there are *five* independent endemic centers of the disease: (1) The province of Tripoli; (2) Southwestern Arabia; (3) A large section of Asia, including Mesopotamia, Persia, and Kurdistan; (4) The districts of Kumaon and Gurwhal in northwestern India; and (5) Southwestern China. Robert Koch considers there are *three* endemic main plague foci in Asia—viz., Mesopotamia, Thibet, and Assia, while he places the primary source of the disease in the English territory at Uganda ("Sajous' Annual," vol. v., 1900). In addition to the recent epidemic in China the region of the lower Volga and neighboring Turkey was visited as recently as 1878 and 1879.

Etiology.—The epidemic of 1894 gave the opportunity of isolating the specific germ of plague which was discovered by Kitasato and later by Yersin. It is a short rod with rounded ends, and resembles the bacillus of chicken cholera. It is found in the blood, glands, and other viscera, and in no other disease excepting the plague. Obtained in pure cultures, it can produce in inoculated animals the same effects as in human beings. It obtains entrance through the respiratory and digestive tracts, but especially by way of excoriations. It occurs generally in pure culture, but may be associated with pus-forming bacteria, which enter the system with it or after it and are responsible for the suppuration. Filth is a potent predisposing cause, as the description of Dr. Aoyoma, who was a member of Kitasato's expedition and himself fell a victim, vividly portrayed. The rat is a medium of transmission from house to house, while man in his travels is the agent of transmission through long distances. Flies, fleas, ants, and other insects may transmit the disease, while almost any of the lower animals are subject to it.

Plague is a disease of hot countries and of hot seasons, but it may break out in midwinter. It attacks all ages and classes, but the poor, who live in

* For an admirable series of papers on the Plague see "British Med. Jour.," October 27, 1900; also, "Bubonic Plague," by Simon Flexner, M. D., "University of Pennsylvania Medical Bulletin," November, 1902.

crowded quarters and amid unfavorable hygienic surroundings, are its favorite victims. The fact that small animals such as monkeys, squirrels, rats, and mice die in great numbers during epidemics and seem, indeed, to be the first victims, suggested that the specific organism is of telluric origin. At any rate, the bacilli have been found in the soil and dust of houses inhabited by its victims. In this respect it is similar to anthrax and tetanus. Persons who live in upper stories are less frequently attacked than those who live on the ground floor. The boating population of China, which lives mostly on the water, is comparatively exempt. Body linen, bed clothing, carpets, rags, and baggage are frequent media of communication.

On the other hand, virulent as is the plague, its contagium appears to be more controllable than that of such diseases as smallpox and scarlet fever, as evidenced by the fact that with ordinary cleanly precautions few physicians, nurses, or others attendant on the sick acquire the disease, and even those employed to guard and disinfect infected houses commonly escape. In the epidemic in Canton, during which upward of 30,000 Chinese died, not one of 300 American and English residents was affected.

Morbid Anatomy.—There is no morbid anatomy to the plague beyond the buboes and internal suppurating processes, which seem to be essential symptoms, the cutaneous and other hemorrhages, and the various tissue alterations that attend high fevers generally. The liver and kidneys are congested and the spleen is enlarged to two or three times its normal size.

Varieties of the Disease.—Three principal forms are easily separated: (1) *Pestis minor*, abortive or larval form, which commonly appears before the outbreak of an epidemic. It is also the form which is endemic. It is characterized by moderate swelling of the lymphatics, little fever or other constitutional disturbance, and usually terminates favorably at the end of about two weeks. (2) *The bubonic form* is the more common severe epidemic form—the *malignant adenitis* of James Cantlie. Until recently all plague was called "bubonic," but it is now known that only about 70 per cent. of cases are accompanied by glandular enlargement. (3) *The septicemic form*, also known as *toxic*, *fulminant*, or *siderans*, a severe form, in which death may occur in twenty-four hours with associated hemorrhages, but in which glandular enlargement is slight; the time between the onset and the fatal termination being too short to allow its development. Prostration is extreme. (4) *The pneumonic form*, in which no buboes appear on the surface, but the force of the disease is spent on the lungs, the sputum swarming with bacilli. The processes in the latter organs are septicemic.

Symptoms.—*Of the bubonic or ordinary form.*—A *period of incubation* of from two to seven days usually precedes the appearance of the *intense weakness* which is one of the earliest characteristic symptoms of the plague. A second period or *period of prodrome* may follow the incubation, though it is not common. It is short, from a few hours to a couple of days, and includes headache, prostration, marked nausea, vomiting, vertigo, and rarely lumbar pain. A chill is not usual, but there may be *chilliness*, after which the usual *fever* of the infectious diseases sets in with great severity and with its accompaniments, among which severe headache, backache, delirium, and the typhoid state are conspicuous. The *temperature* rises rapidly to 102° and 104° F. (39° and 40° C.) and even higher. The *pulse* ranges from 90 to 120, of fair volume, often dicrotic. Before the fever sets in great weak-

ness is manifest. The patient reels like a drunkard, with weakness and vertigo. He breathes hurriedly and is anxious, restless, and depressed. The features are drawn and haggard. *Petechiæ, vibices*,—the plague-spots of the Bible,—*albuminuria, hematuria*, and even *hematemesis* may be included. Slight enlargement of the spleen is present.

Pre-eminently characteristic is the *bubo* or suppurating gland. It appears on the second or third day, if the patient live to it. It occurs in order of frequency in the glands of the groin, the armpit, the neck, or in the popliteal region. It commonly reaches the size of a walnut or egg, when it ruptures, if not opened with the lance. It may, however, subside without discharging. Suppuration is a desirable termination. It is painful and tender, as buboes commonly are. Coincident with the appearance of the bubo the fever subsides, a *profuse sweat* breaks out, and the pulse falls to 90 or 100. In addition to the bubo, *carbuncles* may also be present in the lower extremities, the buttocks, or in the neck. In some epidemics hemorrhages are common, and even the buboes may contain blood.

In the *pneumonic* form there are the usual symptoms of pneumonia, chill, high fever, severe pain in the side, dyspnea, cough, rusty sputum, and physical signs of consolidation,* and marked prostration.

In the *septicemic form* the patient is stricken by a virulent poison and the prostration is extreme. The glands are enlarged, but there are no buboes. The enlargement is slight and may only be detected at necropsy, but it is general. Hemorrhages from the nose, bowel, and kidney are most frequent in this form. Apyrexia is not uncommon, fever reaction being impossible because of the extreme depressing influence of the disease. The delirium is of the typhoid type.

Diagnosis.—In its fever, its intense prostration, its petechiæ and vibices of the early stages the plague resembles typhus. No other fever is characterized by such intense prostration. The bubo and the carbuncle seem to be the distinctive signs, although they are said to be sometimes absent in the milder cases of a declining epidemic, as well as in the intense *pestis siderans*. The diazo reaction of the urine is usually absent.

Prognosis.—The plague is said to be the most fatal of all diseases, 70 to 90 per cent. perishing, districts and towns being half depopulated, while whole families have been annihilated. Death occurs from the second to the fourth day, and if recovery take place it is delayed by the slowly healing buboes and carbuncles. These may, however, heal rapidly.

Treatment.—Free stimulation, nutritious food, as in the most adynamic forms of typhus and typhoid fevers together with cool baths to combat the fever, are the measures indicated. Antiseptic treatment of the buboes and abscesses should be practiced, and may shorten the duration of these plagues of the skin as compared with the older treatment. Morphin should be given to produce sleep and relieve pain. Kitasato's general directions, so often quoted, can hardly be improved. They are as follows:

"The disease prevails under faulty hygienic conditions; it is, therefore, urged that general hygienic conditions be carried out. Proper receptacles for sewerage should be provided, a pure water supply afforded, and streams cleansed; all persons sick of the disease isolated; the furniture of the sick-room washed with a two per cent. carbolic solution in milk of lime; old clothes and bedding are to be steamed at 100° C. (212° F.) for at least one

* For reports, see "Sajous' Annual," vol. v., 1900, article "Plague."

hour, or exposed for a few hours to sunlight. If feasible, all infected articles should be burned. The evacuations of the sick are to be mixed with milk of lime, and those who die of the disease are to be buried at a depth of three meters (about 12 feet) or, preferably, cremated. After recovery the patient is to be kept in isolation at least one month. All contact with the sick is to be avoided, and great care exercised with reference to food and drink." Instead of carbolic acid and milk of lime for the disinfection of buildings, Haffkine suggests sulphuric acid in the proportion of 1 to 200 of water.

Serum Therapy.—Preventive inoculation was introduced by Yersin, Calmette, and Borrell conjointly in 1895. Dead cultures of plague bacilli were injected subcutaneously into rabbits and guinea pigs and found to convey a certain degree of immunity against plague. Haffkine extended this method of preventive inoculation to man. The dead bacilli, suspended in bouillon, are injected subcutaneously. These injections were first made upon lower animals, notably monkeys, with the result of protecting them against subsequent inoculation with virulent plague bacilli; then upon human beings in India and China.

The results of these inoculations are more definitely stated in the following conclusions reached by the Indian Commission: "(1) Inoculation sensibly diminishes the incidence of plague attacks on the inoculated population, but the protection which it affords against attacks is not absolute; (2) Inoculation diminishes the death-rate among the inoculated population. This is due not only to the fact that the rate of attack is diminished, but also to the fact that the fatality of the attacks is diminished; (3) Inoculation does not appear to confer any great degree of protection within the first few days after it has been performed; (4) Inoculation confers a protection which certainly lasts for some considerable number of weeks. It is possible that the protection lasts for a number of months. The maximum duration of protection can only be determined by further observation; (5) The varying strengths of the vaccine employed have apparently had a great effect upon the results which have been obtained from inoculation. There seems to be a definite quantum of vaccinating material which gives the maximum amount of protection; and provided that this quantum can be injected in one dose, and provided also that the protection turns out to be a lasting one, reinoculation might with advantage be dispensed with."*

As contrasted with preventive treatment Yersin's antipest serum † and Lustig's serum are intended for curative purposes, after the manner of diphtheritic antitoxin. The former is prepared by injecting the horse, first, with dead and then with living plague cultures. The serum, to insure sterility, is heated to 60° C. (140° F.) before being sent out. Lustig's serum is prepared from the horse after injection with a substance derived from bacilli by treatment with alkali and precipitation by hydrochloric acid.

Small animals have been rescued from infection by plague germs by Yersin's serum, but in human beings the results have been less conclusive, Arnold ‡ claiming that it reduced the mortality of cases 70 to 90 per cent., while Cremow § denies any therapeutic value. Calmette and Salimbini claim to have shown from their observations and experiments during the plague epidemic in Oporto, Portugal, that much larger doses of the antipest serum

* See Dr. Simon Flexner's paper on "Bubonic Plague, its Nature, Mode of Spread, and Clinical Manifestations," "University of Pennsylvania Med. Bulletin," November, 1902.

† "Sajous' Annual," vol. v. p. 491.

‡ "Med. News," January 1, 1898.

§ "London Lancet," May 6, 1899.

may be used, and are sometimes demanded, than have heretofore been deemed sufficient. Their report also shows that, while the use of the Haffkine prophylactic may be attended with danger among those who have been exposed to the infection of the disease prior to inoculation, the use of a preliminary immunizing dose of antipest serum, followed by an injection of a dose of Haffkine's prophylactic, removed the element of danger and conferred an immunity of probably longer duration than would be produced by the exhibition of the serum alone.

Notwithstanding the seeming inconclusiveness of these observations, the Indian Commission reports that "though the method of serum therapy as applied to plague has not been crowned with a therapeutic success in any way comparable to that obtained in the treatment of diphtheria, nevertheless, the method of serum therapy is in plague, as in other infectious diseases, the only one which holds forth the prospect of success."

Walter Wyman, Supervising Surgeon-General United States Marine Hospital service, has directed that between 160 and 200 c. c. of antipest serum should be given during the first forty-eight hours of the disease. In severe cases, 20 to 40 c. c. of this amount should be injected into a vein. In immunizing with the serum, use 5 to c. c. every fifteen days. In case the Haffkine prophylactic cannot be administered on account of exposure to the disease, the mixed plan of immunization may be used. This consists of giving 5 to 10 c. c. of antipest serum, and, three days later, 1 c. c. of the Haffkine prophylactic.*

MEASLES.

SYNONYMS.—*Rubeola*; *Morbilli*.

Definition.—Measles is an acute, highly contagious disease, characterized especially by a mottled eruption and nasobronchial catarrh.

Historical.—Measles and smallpox are first recognized in the writings of Ahrun, a Christian priest and physician of Alexandria, A. D. 610-641. It was, however, first accurately described by Rhazes, A. D. 900, and Avicenna, A. D. 980-1037. Rhazes is accredited with distinguishing it from smallpox. It continued, however, to be confused with the latter disease as late as the middle of the seventeenth century. The two were clearly separated by Withering as late as 1792. The distinction of having separated the disease from scarlet fever was awarded to Thomas Sydenham about 1665, but this separation is also said to have been made one hundred years earlier—that is, in 1563—by Forestus, of Holland. Rhazes and Avicenna described it under the name *hhasbah*. The term *rubeola* or its equivalent in Arabic is said to have been first used by the Arabian, Haly Abbas, in the latter part of the tenth century, but was replaced by the Italian word *morbilli*, meaning little disease, up to the middle of the eighteenth century, when Sauvages reapplied the name *rubeola*, which was adopted by Cullen and Willan. Within the last few years some English writers have reapplied the name *morbilli*. The disease has prevailed in Asia and Europe for centuries, and was imported into the United States with the first settlers.

Etiology.—Measles is in all probability due to a micro-organism, which, however, has not as yet been isolated, although micrococci have been found in the blood and tracheal mucus by Babes and by Klebs. More recently, 1892, P. Canon and W. Pielicke † found with considerable constancy a bacillus in the blood, the expectoration, and nasal and conjunctival mucus of cases of measles. Whatever it is, it is very unerring, since the dis-

* "Philadelphia Medical Journal," February 10, 1900.

† "Berliner klin. Wochenschrift," vol. xxix. 377.

ease is more unfailingly communicated to those unprotected by previous attacks than is scarlet fever. Nor is the contagium-bearer definitely known, but it is likely to be the nasal and bronchial discharges, and probably also the tears. The contagium has been transmitted by the inoculation of morbillous blood and nasal mucus, and it is most active when the breath is its medium. It is communicable by a third party and by fomites; though more active and unailing than the contagium of scarlet fever, it is less so than that of smallpox. It is not, however, so tenacious as the causes of these. Measles is a disease of childhood, but adults often get it, and that very severely. Repeated attacks are possible, but as other eruptive affections resemble it and diagnosis is often careless, some of the repeated attacks may be thus explained. It is milder and rarer in sucklings under six months, while the age during which the disease is more commonly contracted is from one to five years.

Morbid Anatomy.—There is no essential morbid anatomy of measles beyond the nasal and bronchial catarrh, and the signs of these generally disappear with death. When death occurs it is usually the result of complications, and the morbid anatomy of such is present. The most frequent com-

Fig. 13.—Temperature Chart of Measles—(Eichhorst).

plication is bronchopneumonia. There may be lobar pneumonia, and among the morbid phenomena are to be included sometimes those of collapse of the lung. In those rare instances of hemorrhagic or “black” measles there is the usual discoloration of hemorrhagic extravasation. Rarely also the morbid states of intestinal catarrh are found.

Symptoms.—The *period of incubation* of measles varies, but is commonly between seven and fourteen days. Rarely it is a day or two longer. A prodrome, if present, in measles is of short duration. It may be manifested by sneezing, fretfulness, chilliness, and feverishness; or, if the child is old enough to express itself, by headache. Then comes, on the first day, the initial or prodromal fever, a peculiarity of which is a remission on the second day. This is shown by the appended cut from Eichhorst. But very early,

and even almost suddenly, *coryza*, with red and watery eyes, and photophobia present themselves, closely followed by troublesome *cough* and corresponding feverishness reaching 103° and 104° F. (39.4° and 40° C.). Much less frequently than in scarlet fever is there *vomiting*, but the *tongue* is apt to be furred; the cough is sometimes croupy. Convulsions very rarely usher in the disease.

On the fourth day from the onset the *eruption* makes its appearance. It appears first in the face in the form of papules and blotches, which coalesce more or less imperfectly, leaving sometimes islands of white skin between them. Under any circumstances the boundary between the eruption and the sound skin is uneven and crescentic. The eruption is somewhat raised above the surface, and the whole effect is to make the face appear swollen. This elevation of surface at times becomes distinctly papular and even shot-like, resembling closely the papular stage of smallpox. In fact, this appearance has quite often led to a diagnosis of smallpox, which twelve hours later had to be withdrawn. From the face the eruption spreads to the neck, thorax, abdomen, and extremities. It is bright red, as a rule disappearing on pressure. Sometimes, however, even in mild cases, there are petechiæ, and in malignant cases the extravasations are extensive. At the same time, the mouth and fauces are bright red in color, and not infrequently there is diarrhea, as though the eruption extended throughout the entire mucous tract as well as over the skin. At the maximum of the eruption there may be slight swelling of the cervical lymphatic glands. At the end of two or three days after its appearance the rash fades gradually, first from the situations in which it appeared earliest, and a fine, branny desquamation occurs, easily overlooked. The fading takes place in the order of invasion. The typical rash may be accompanied by sudamina.

In 1896 Henry Koplik* called attention to a sign that seems likely to be of real value in the diagnosis of measles. It is the appearance, on the first day of invasion, on the buccal and labial mucous membrane, of a scattered eruption consisting of small irregular spots, *bright red in color*, in the center of which is a minute *bluish-white speck*. They have been found 45 times in 52 cases and 31 times in 32 cases. The spots somewhat resemble those of thrush, from which they are distinguished by their roundish shape and their color, as contrasted with the more *yellowish* center of those of thrush. While thoroughly discrete in the beginning, later in the disease the spots may coalesce, and the characters of a discrete eruption or spotting disappear, producing an intense general redness, "which is simply dusted over with myriads of these bluish-white specks." They cannot be wiped off, but the whitish portion can be removed by forceps without causing pain or bleeding. They consist of thick layers of epithelium in a state of partial fatty degeneration. They require a good light for their demonstration. (See plate opposite.)

The other symptoms described continue until the eruption begins to fade—that is, on the fifth or sixth day, when they abate. The *cough*, except at times, often hangs on quite stubbornly, especially in scrofulous children, and sometimes even persists as the catarrhal symptom of a tuberculosis, the development of which seems peculiarly favored by the disease. Hence, the cough of measles should never be slighted, and early exposure to cold and dampness should be guarded against.

FIG. 4.

THE PATHOGNOMONIC SIGN OF MEASLES (KOPLIK'S SPOTS).

FIG. 1.—The discrete measles spots on the buccal or labial mucous membrane, showing the isolated rose-red spot, with the minute bluish-white centre, on the normally colored mucous membrane.

FIG. 2.—Shows the partially diffuse eruption on the mucous membrane of the cheeks and lips; patches of pale pink interspersed among rose-red patches, the latter showing numerous pale bluish-white spots.

FIG. 3.—The appearance of the buccal or labial mucous membrane when the measles spots completely coalesce and give a diffuse redness, with the myriads of bluish-white specks. The exanthema on the skin is at this time generally fully developed.

FIG. 4.—Aphthous stomatitis apt to be mistaken for measles spots. Mucous membrane normal in hue. Minute yellow points are surrounded by a red area. Always discrete.

—(From "Medical News.")

It has already been intimated that a malignant form of measles sometimes occurs, called also "black" measles, which is very serious—often, indeed, fatal. It is generally epidemic, occurs in institutions and camps, and its presence is characterized by subcutaneous extravasations of blood and hemorrhages from the mucous membranes.

Complications and Sequelæ.—These furnish most that is serious in the disease, and of these the most frequent and dangerous is catarrhal pneumonia or bronchopneumonia, the bronchitis creeping into the smaller air-tubes. The occurrence of this form of pneumonia seems to be favored by bad hygiene. Collapse of the lung is also prone to occur, caused by an accidental valve-like plug of secretion. Bronchopneumonia is recognized by the persistent and aggravated cough, the continued high temperature, and physical signs of a circumscribed pneumonia. More rarely lobar pneumonia supervenes and is recognized even more easily. In view of these possible complications, frequent physical examinations of the chest should be made.

Among the complications may be mentioned laryngitis, catarrh of the middle ear leading to suppuration and perforation of the drum, and chronic or intractable ophthalmic trouble. Ulcerative and even gangrenous stomatitis are met under unfavorable hygienic conditions.

Nephritis, although not often a complication of measles, does, however occur, and I have met serious instances of such. Tuberculosis has long been recognized as a sequel of measles, yet it is not a very frequent one. Any of the varieties of pulmonary tuberculosis may be present. Even nervous lesions are reported, such as hemiplegia, paraplegia, neuritis, and myelitis.*

Diagnosis.—Measles is easy of diagnosis; but the physician must not be too precipitate. Allusion has already been made to the possibility of mistaking it for *smallpox*, on account of the similarity of the eruption in the early stage, an error which a few hours' delay would have averted. Koplik's spots should be helpful here, as they are said to appear at least twenty-four hours before the skin eruption. From *scarlet fever* there is sometimes difficulty, as there is occasionally slight sore throat and the eruption may be diffuse, while the difficulty is increased if there be glandular swelling in measles; but the catarrhal symptoms of measles are essential to it. The mildest cases are probably those that give most trouble. The distinction between measles and rubella is sometimes more difficult, but this will be considered when treating of rubella.

Typhus fever and measles have been confounded, and it must be admitted that in the asthenic variety of measles the eruption may resemble that of typhus fever. It will be remembered that the eruption of typhus is described as "rubeoloid." Confusion is further favored by the fact that the eruption occurs at about the same time in each disease.

Prognosis.—The vast majority of cases of measles get well. It is only in epidemics of the malignant form, in hospitals, camps, and foundling asylums, that death occurs as a direct result of the disease. In these the mortality is sometimes very high. Epidemics among the aborigines in North and South America, in the Mauritius and Feejee Islands, and in the Confederate Army in the War of the Rebellion in America were of signal fatality. Other deaths are due to complications, especially pneumonia. Out of 24 fatal cases collected by Pott, 21 died of bronchopneumonia and pneumonia, and 3 of croup.

* See a paper by Imogene Bassette entitled "The Paralysis in Children which Occur during and after Infectious Diseases," "Jour. Nerv. and Ment. Dis.," vol. xix., 1902.

Treatment.—After surrounding the patient by a uniformly warm temperature, best secured in bed, the treatment of measles is mainly that of the fever and the cough. The former is sufficiently treated by the simple diaphoretics and febrifuges, such as citrate of potash and sweet spirit of niter, or tincture of aconite. The latter is efficient and tasteless. The coal tar derivatives, acetanilid, antipyrin, thermol, and phenacetin may be used.

The cough calls for positive anodyne measures, of which, for children, paregoric is the best because the safest. Laudanum or deodorized tincture of opium may be used in smaller doses, but not morphin. They may be combined with the febrifuges just mentioned. It is comparatively rare that cool sponging is needed to reduce the temperature, but cold water drinking should be allowed *ad libitum*. I recently knew a case of measles to receive the cold tub-bath treatment under the impression that it was typhoid fever. The rash came out brilliantly at the proper time and the case did splendidly. Complications should be treated as they arise. Stimulants and tonics are necessary in the adynamic form. When the cough is prolonged, cod-liver oil is a valuable remedy. Watchfulness during convalescence is more important than is supposed by many, and carelessness and indifference are sometimes responsible for unfortunate results.

It occasionally happens that the eruption is "suppressed," or its appearance may be delayed. Under these circumstances the hot pack is very effectual. The child is wrapped in flannel wrung out in hot water and then enveloped in a mackintosh. Copious perspiration soon sets in, the eruption appears, and general reaction begins.

I have never seen any good reason for isolating measles as usually occurring in families. The disease is so mild in children, and so much more serious in adults, that I believe it is desirable that all the children of a family should have it as soon as possible.

RUBELLA.

SYNONYMS.—*Rötheln*; *Rubeola*;^{*} *German Measles*; *Rubeola notha*; *Epidemic Roseola*; *False Measles*; *Hybrid Measles*; *Hybrid Scarlet Fever*.

Definition.—Rubella is a mild, acute, contagious disease, characterized by a punctiform rash that fuses into patches less plainly crescentic than those of measles. There is often slight sore throat, more rarely mild catarrhal symptoms, and trifling fever. Many so-called second attacks of measles and scarlet fever are attacks of rubella.

Historical.—The existence of rubella as an independent and separate infectious disease was for a long time disputed, some regarding it as a variety of measles and others as a mild form of scarlet fever, although as far back as 1752 Bergen, a German physician, claimed for it a distinct individuality. A sufficient foundation for such claim was not, however, advanced until 1815, when Maton, an English physician, substantiated that, while one attack protected ordinarily against its own recurrence, it did not protect its victim either from measles or scarlet fever, while an attack of either of the latter diseases did not protect from rubella. A few held out for the original views, among whom was the eminent Hebra, but there seems to be no one at the present day who denies that it is an independent disease. The name "rubella" was first suggested by Veale in 1866.

^{*} It is unfortunate that the Germans have selected for their technical term for this affection the word *Rubeola*, which is the word used in English for *measles*.

Etiology.—The relation of the disease seems rather closer to measles than scarlet fever, and may be said to bear to the former the same relation as varicella to variola. Though contagious, it is much less so than measles or scarlet fever. It affects children chiefly, very rarely adults, sucklings less frequently than school children, because the latter are more exposed to contagion. Isolated cases occur, but it is apt to prove in large cities epidemic. Such epidemics are sometimes widespread.

Symptoms.—After a *period of incubation* ranging from two to three weeks, the disease sets in, as a rule, with no distinctive symptoms of invasion prior to the eruption. There may be chilliness, moderate muscular pain, mild catarrh, and slight fever, with temperature barely reaching 100° F. (37.8° C.), for a day or two previous to the eruption. More frequently, an indistinct macular *eruption* of a pale rose color is first noted. The papules are scarcely elevated, and vary in size from a pinhead to a split pea, the smaller being more numerous, much smaller than the papules of measles. They may, however, fuse and form large, irregular patches, with little or no disposition to form small crescent-shaped groups like those of measles. The rash may appear as late as the second day, rarely on the third, after the indistinct symptoms of invasion mentioned.

Two types of the spread of the eruption are possible. In the one it appears almost simultaneously all over the body, reaching its maximum by the second day, after which it rapidly fades. In the second mode of invasion the rash appears first on the face, and extends rapidly thence all over the body, reaching the hands and feet last, and beginning to fade on the face and trunk before attaining its maximum on the extremities, or even before it appears there at all. Thus it has a wave-like course, reaching its maximum in twenty-four hours, when it begins to decline rapidly. It is, therefore, of shorter duration than the eruption either of measles or of scarlet fever. It may terminate in a branny desquamation, less evident even than that of measles.

The most constant symptom after the eruption is the *sore throat*. It varies in severity, but is for the most part mild, never becoming ulcerative. It is really, perhaps, the eruption in the throat. Somewhat less constant than the sore throat, though varying somewhat in different epidemics, is *swelling of the lymphatic glands* of the neck, especially the superficial cervical, postcervical, and postauricular glands. This swelling is present during the eruptive stage and may occur even earlier. Its possible, though rarer, occurrence in measles also is to be remembered.

The remaining symptoms of rubella are not marked nor distinctive. There is little or no constitutional disturbance, and, as already mentioned, rarely any *fever* above 100° F. (37.8° C.), although 102° F. (38.9° C.) and even 103° F. (39.4° C.) have been noted. There may be slight catarrh, watering of the eyes, and running at the nose, all much less marked than in measles. There are no complications, as a rule, though albuminuria, nephritis, pneumonia, colitis, and icterus have been reported, but it would seem as though measles or scarlatina must have been mistaken for rubella in these cases.

Diagnosis.—Such are the symptoms of a typical case. Unfortunately, there are many deviations, some approximating *measles* and some *scarlet fever*, differing from either mainly in mildness. The absence of decided catarrhal symptoms, the earlier appearance of the eruption, its more diffuse character, and the swelling of the lymphatic glands are its chief differences.

from measles. The careful studies of J. P. C. Griffith * show the latter of less significance than has been usually supposed. The course of the eruption differs also, that of measles lasting longer. The absence of Koplik's sign must hereafter be helpful in distinguishing it from measles. The same mildness and absence from fever, with the more distinct mottling, distinguish it from scarlet fever. In rubella the symptoms of invasion are all very much milder than in either measles or scarlet fever, even mild cases of the latter.

Prognosis.—The prognosis of rubella is invariably favorable.

Treatment.—Very little if any is required, except rest in bed. A simple febrifuge with potassium chlorate may be useful.

SCARLET FEVER.

SYNONYM.—*Scarlatina*.

Definition.—Scarlet fever is an acute contagious disease, especially characterized by faucitis and a diffuse scarlet eruption, terminating in more or less membranous desquamation.

Historical.—Although it has been claimed that the pestilence of Thebes, 600 B. C., and the plague at Athens, 430 B. C., were each epidemics of scarlet fever, no accurate knowledge of this affection as a separate disease was obtainable prior to the seventeenth century, when Sydenham and his contemporaries described it in a manner which permits its easy recognition as the scarlet fever of to-day. It pervades the Old World everywhere, having been recognized in England in 1661, Scotland in 1716, Germany and Italy in 1717, Denmark in 1740, and was introduced into North America by shipping in the year 1735. It did not, however, reach South America until 1829, Iceland 1827, and spread to Greenland as late as 1847.

Etiology.—The organism that causes scarlet fever has not been isolated. Streptococci have been found in the blood and postmortem in the lymphatic glands and kidneys.† Whatever the agency, it is the most tenacious of all the contagia, retaining its power to infect for at least a year after the occurrence of a case. It is especially difficult to dislodge from organized substances, such as bedding, clothing or straw, letters and books, and the disease has been communicated to newcomers even after an infected apartment has been thoroughly cleaned and fumigated with sulphur. Physicians have doubtless conveyed it, and the beard and hair are contagium-bearers more frequently than is supposed. Hence, physicians should not wear long beards, and nurses, before passing from one case to another, should disinfect their hair as well as the rest of their body.

While the contagium itself has never been isolated, there is every reason to believe that the bearer is the exfoliated epithelium. Hence, it is not until desquamation takes place that the disease is communicable, and the ease with which the scaly particles are disseminated through the air and the tenacity

* "Differential Diagnosis of Rubeola and Rubella, with Special Reference to Enlargement of the Glands of the Neck," *University Med. Magazine*, June, 1892.

† Dr. William J. Class ("Monthly Bulletin of the Chicago Dept. of Health," March, 1899) claims to have found a diplococcus which fulfills the conditions that make it reasonable to believe it is the bacterium responsible for scarlet fever. His observations are confirmed by Calvin G. Page, in a "Preliminary Report on the *Diplococcus of Scarlet Fever*" (*Journal Boston Society of Medical Sciences*, March 24, 1900), by K. H. B. Gradwohl (*Philadelphia Med. Jour.*, March 24, 1900, p. 683), and W. K. Jaques (*Ibid.*, March 10, 1900, p. 552). The diplococcus was found in the throat, blood, and desquamative scales in a large proportion of cases by all these observers. In a further paper in the *Philadelphia Med. Jour.*, June 23, 1900, Dr. Class describes his efforts to obtain an antitoxin. The bacillus of Class is, however, not regarded by the best-trained pathologists as the cause of scarlet fever.

with which they adhere to textures readily explain the communicability of scarlet fever and the difficulty in destroying its cause. On the other hand, until the eruption makes its appearance the disease cannot spread. Accordingly, it is not likely to be communicated to those exposed prior to this stage. Hence, children removed from association with the disease promptly after its discovery, and kept apart, generally escape it.

The route of infection is mostly the respiratory tract, although the alimentary canal may also convey it. In confirmation of this is the fact that in a number of instances milk has been the medium of infection, the milk having been infected by exposure in an apartment occupied by patients. In one instance the disease appeared in six out of twelve families supplied from such a source. The readiness with which milk absorbs volatile substances kept in the same refrigerator compartment and retains their flavor is quite in accord with such transmission.

Children of either sex are more subject to the disease, because a single attack, as a rule, protects against a second. Infants, however, even under exposure, are less liable to the disease, and it would seem, too, that adults who have escaped exposure during childhood are less liable. I have never had scarlet fever, and have been exposed many times to the most virulent forms. The primary attack is not always protective; second and third attacks are reported. But here, again, careless diagnoses and defective memory are responsible for a certain number. In my own experience the disease is most common about the age of seven.

Morbid Anatomy.—There is no morbid anatomy peculiar to scarlet fever. The eruption fades after death, unless there happens to be hemorrhagic extravasation. There may be lesion the result of ulcerative destruction in the neighborhood of the throat. The intensity of the fever sometimes produces granular fatty change in muscles, which is pronounced in the case of the heart; also cloudy swelling in the cells of the kidney and liver. Glandular swellings present at death maintain themselves afterward. The morbid anatomy of the complications and sequelæ is appropriately considered under the diseases constituting them.

Symptoms.—The *period of incubation* varies greatly. It is sometimes as short as twenty-four hours, and again as long as twelve days; more frequently, perhaps, from two to four days. At the end of this time there is usually a very short prodrome, sometimes none at all. *Vomiting*, occurring either as an initial symptom or a couple of hours later, is often present; more rarely a *convulsion*, still more rarely a *chill*. *Sore throat* is early complained of, and high fever is conspicuous. There is early fever, the face is flushed, and the temperature rapidly rises to 103° F. (39.4° C.), 105° F. (40.5° C.), and even 108° F. (42.2° C.), and the pulse to 110, 120, or more.

The *eruption* appears, as a rule, on the second day, and it generally happens that, if it is not present at the physician's first visit, it is sure to be found at his second. Its striking character is its uniform redness. It is like a diffuse, broadly spread blush, appearing first upon the neck and chest, and extending thence rapidly over the whole body, so that at the end of the third day it has completed its invasion. The appearance of a child covered with a frank scarlet-fever eruption is very characteristic. It has been well compared with that of a boiled lobster in its bright redness. It is further characterized by the readiness with which it disappears on pressure and the promptness with which it returns after the pressure is removed. It is, however, no sooner complete than it begins to fade, and does so with great

rapidity in the order of invasion. The eruption is not, however, always thus typical, and presents every degree between that described and that which is barely recognizable. It is also at times more "patchy," but never presents the crescentic or otherwise irregular edges or mottled appearance of the eruption of measles. In the lower and more malignant forms the redness is of a darker or dusky hue, and in the worst of these, petechiæ are present. Vesicles are even found with turbid contents, producing *scarlatina miliaris*. The eruption is sometimes entirely absent from the face; hence no conclusion should be based upon inspection only. The thorax and inner surface of the thighs are more favorable sites. The eruption, when severe, is constantly accompanied by an itching or burning more or less intense, and there is a feeling of slight roughness at times.

The *tongue* is red at the edges and tip, furred at the center, but through the fur the papillæ stand out in distinct points, producing an appearance that is regarded as more or less characteristic. This has been called by some the *strawberry tongue*. So I did in my first edition, but further examination into the subject leads me to adopt the view that the strawberry tongue is the red and raw-looking tongue with enlarged papillæ, as originally held by the late Dr. Flint,* who wrote as follows: "In the progress of the disease the coating exfoliates, leaving the surface of the tongue reddened; and the papillæ being enlarged, the appearance is strikingly like that of a ripe strawberry." The term *raspberry tongue* is also applied to this condition. The rest of the mouth, including the roof and the palate and tonsils, is bright red, as though the eruption extended to it, as it doubtless does.

With the abatement of the eruption comes *desquamation*, and it is generally proportionate to the intensity and extent of the former. It sets in about the *tenth* day, and continues in bad cases for two or three weeks and even longer. When the eruption is slight, the little scales are scarcely noticeable, and the closest examination is necessary to discover them, while, where there is a vivid and extensive eruption, the amount of desquamation is enormous. Glove-like casts of the fingers, including the nails, are sometimes exfoliated, and the bed contains each day numerous flakes of epiderm that have come off, while many days are required for complete separation of the dead skin. Great care should be taken in gathering it up, for in the desquamation resides the contagium. On the other hand, when slight it should be carefully sought for, as it has great diagnostic value. At the same time it should not be regarded as something peculiar and confined to scarlet fever, for every dermatitis is followed by desquamation, as especially exemplified in the exfoliation that follows an attack of erysipelas on the face or irritation by iodine or mustard.

The *urine* from scarlet fever proper is like that of fever cases generally—scanty, high-colored, and precipitating uric acid and urates on cooling. The chlorids are diminished during active fever.

The *duration* of simple uncomplicated scarlet fever ranges from three to fourteen days, according to the degree of severity. Its decline is, however, gradual as compared with the suddenness of onset.

Such is a general picture of scarlet fever in its simple, uncomplicated form, so characteristic that early in its history it received the name *scarlatina simplex*; owing to further combinations of symptoms, there have been

* For an interesting paper containing the views of various authors on this subject see "The Strawberry Tongue in Scarlet Fever," by M. H. Fussell, M. D., "University Med. Magazine," Philadelphia, May, 1897.

Fig. 14.—Temperature Chart of Scarlet Fever.—(Eichhorst).

added three other varieties: the anginose form, or *scarlatina anginosa*; the malignant form, or *scarlatina maligna*, and the *hemorrhagic* form.

In the *anginose* variety the throat symptoms are conspicuous and severe. In no well-developed case is there an absence of throat redness. On the other hand, there may be intense soreness with swelling of the fauces and tonsils, giving rise to extreme dysphagia. The neck may be so swollen as to fill up the depression beneath the jaw. There may be a false membrane involving the fauces, the posterior pharynx, the nasal cavities, the trachea, and the bronchi. The throat may present all the features of a severe diphtheria. Abscess and destructive ulceration may result, which may proceed even to perforation of the carotid artery, and rapid death ensue therefrom. The inflammation almost certainly ascends the Eustachian tubes, producing severe ear symptoms. The false membrane is usually the result of the intensity of the inflammatory process, due to the specific cause of the disease and not to that of diphtheria, but there may be true diphtheritic membrane containing the Loeffler bacillus. Especially is this true of the cases in hospitals for infectious diseases. The *streptococcus pyogenes* is perhaps the most frequent cause of the throat inflammation. It has been found also in the skin, the blood, and the glandular organs in fatal cases. Scarlet fever has, indeed, been called a streptococcus infection. Follicular tonsillitis may also be one of the forms of sore throat.

In the *malignant* variety there is an overwhelming intensity of the cause which may result in almost immediate prostration and death of the patient, giving no time for the development of the usual symptoms, or these may be so feebly manifested that they present no distinctness. When the disease is not immediately fatal, there is intense adynamia, the heart and pulse sharing it. The breath is rapid; the capillary circulation is feeble; the skin dusky; the eruption is imperfectly developed; the temperature is very high, reaching 105° to 108° F. (40.5° to 42.2° C.): there is delirium, which may pass over into coma, and convulsions may occur. The pulse ranges from 120 to 150.

In the *hemorrhagic* form there are more or less extensive hemorrhagic extravasation, epistaxis, and hematuria. It attacks, for the most part, the feeble and badly nourished, and, like the previous variety, is almost invariably fatal.

Epidemics of scarlet fever vary greatly in severity. In some all the cases appear to be mild, in others all are of extreme severity. Families of children may be exterminated. Again, a mild case may give rise to one of the most intense forms.

Complications.—*Acute nephritis* is the most frequent complication of scarlet fever. It makes its appearance usually after desquamation is more or less complete—in the second, third, or fourth week. A slight albuminuria, which is common at the height of the fever, is not to be confounded with that of nephritis, and probably does not predispose to it, although the cells lining the tubules are at this stage in a state of cloudy swelling. The rationale of its production is not precisely understood. It used to be ascribed to cold or a draft of air upon the skin, which is young and tender after the desquamation. But when it is remembered that the mildest cases are as susceptible as the most severe, and probably more so, and that children have been found barefoot in the street with the eruption upon them, and yet have escaped Bright's disease, it must be admitted that we do not know all about it. The fact that the complication is usually more severe the earlier it appears, would go to show that the specific toxin or bacillus has

something to do with it. It is true, too, that with the skin functionally dead the complementary work thrown upon the kidney increases its susceptibility to the ordinary causes of nephritis, of which cold is one. It is to be remembered also that other diseases in which the skin is seriously affected predispose to nephritis. This is pre-eminently true of burns and scalds.

However it may be brought about, the result is generally a typical example of parenchymatous or tubal nephritis, although instances of acute interstitial inflammation are also found. Every grade of severity is met, but early recognition increases our power to control this severity. The majority of cases thus recognized get well, and I have known recovery to take place after suppression of urine has lasted for a week. The clinical picture is that of acute nephritis otherwise caused, and its consideration may be deferred until that disease is studied. This complication was formerly often overlooked, but in modern times cases are more closely watched for it. The possibility of Bright's disease without albuminuria must be borne in mind.

Adenitis producing a moderate degree of glandular enlargement occurs in almost all cases of scarlet fever, but in severe cases it becomes a painful and grave complication. A majority of cases subside, but some go on to extensive and destructive suppuration, of which I have known ulceration through the carotid artery a consequence.

Arthritis ensues in a certain number of cases, and closely resembles that of acute rheumatism. The term rheumatism is justified as much as the term gonorrhoeal rheumatism, and no more. Each is the result of the specific cause of the disease, and not of the cause of rheumatism. It occurs usually at defervescence, and recovery is almost invariable. Suppuration in the joint has, however, occurred.

Otitis is one of the most serious and permanently harmful of the complications. It is commonly considered the result of an extension of inflammation from the throat through the Eustachian tube to the middle ear, and is associated with the streptococcus. I have known it to occur after recovery was supposed to have taken place, immediately after a child had been sitting on a cold step. On the other hand, it sometimes happens quite early in the disease. Suppuration and perforation of the membrane of the tympanum are common, and more rare is destructive suppuration of the mastoid cells. As a consequence of one or both of these, it almost always leaves impaired hearing or total deafness. The facial nerve may become involved in the disease of the labyrinth, producing facial palsy, while thrombosis of the lateral sinuses may be another result of the same condition. Meningitis and death may be later consequences.

Meningitis may arise independently of otitis; in fact, scarlet fever is the most frequent cause of meningitis, after cerebrospinal fever, tuberculosis, and syphilis.

Various other *nervous affections* develop as rare complications. Among these may be mentioned chorea, convulsions, hemiplegia; and Osler mentions two cases of progressive paralysis of the limbs due to ascending spinal paralysis or multiple neuritis and subacute ascending paralysis as coming under his observation.

Of *thoracic complications* endocarditis and pericarditis not infrequently develop during convalescence from scarlet fever. Endocarditis is not always discovered, and a few unexplained chronic valvular defects may have originated in this way and thus be accounted for. Pericarditis is less likely

to be overlooked. Malignant endocarditis is not so frequent as might be expected from the virulence and widespread character of the responsible germ. Pleurisy may also occur, and more rarely pneumonia.

Diagnosis.—The diagnosis of scarlet fever is easy if the symptoms are well developed, for it is the mild cases that escape detection. In the absence of the eruption in a distinctive form, it is sometimes impossible to aver the presence of the disease. If there be a doubt as to the eruption, close watching will sometimes discover signs of desquamation in the shape of branny scales beneath the underclothing or in the stockings. In the absence of this the question must occasionally remain forever unsettled. At others the unfortunate development of a nephritis sets the matter at rest. If there has been exposure to the contagion, it is best to regard every case of sore throat as a possible case of scarlet fever, and treat it accordingly. While the throat affection of *diphtheria* closely resembles at times that of scarlet fever, where this symptom is at all conspicuous in scarlet fever the eruption is not generally wanting, or is, at least, present to such extent as to permit recognition of the disease. The fact that the one or the other of the two diseases is prevailing may settle the question. It must be admitted, too, that the two affections may succeed each other, and even, perhaps, coexist, both events being, however, exceedingly rare. The diagnosis of diphtheria is rendered certain by obtaining a successful culture of the Klebs-Loeffler bacillus. The facilities furnished at the present day by the municipal laboratories to this end make it easy to obtain this test.

The coryza and cough in *measles* characterize the stage of invasion, while the eruption occurs later than in scarlet fever. When it does come it is very different, being at first, at least, in patches bounded by irregular and crescentic outlines, more uneven and elevated, and is conspicuous in the face, where the scarlet fever eruption is faintest. The absence of sore throat is distinctive of measles, though its occasional presence in mild degree must be admitted in the latter disease.

Rötheln, or rubella, has an eruption more like that of scarlet fever than is the typical measles eruption, but it is not usually followed by desquamation. There are no uncomfortable throat symptoms, and the constitutional disturbance is much less. It is also of much shorter duration. It is possible, too, that these affections may succeed each other, as is true of real measles and scarlatina.

Acute exfoliating *dermatitis* resembles scarlet fever during the eruption, but the exfoliation in the former is not like that of scarlet fever. As in erysipelas, it has more the appearance of scales and crusts before it is thrown off, and there is more apt to be a moist surface left behind, followed by a second exfoliation. There are no throat symptoms, and the tongue characteristic of scarlet fever is wanting. The eruption caused by belladonna, both on the skin and throat, resembles that of scarlet fever, but it is of short duration and without constitutional symptoms.

Prognosis.—The prognosis of scarlet fever varies greatly in different epidemics. There are epidemics of great severity, in which the mortality is large, and certain fulminating cases are beyond treatment. Yet most physicians of large experience in surveying their work will recall that the percentage of deaths in their scarlet fever cases has not been large, and that it has been greatest among the very young. The percentage of deaths is put down at from 5 to 10 per cent. in mild epidemics, and 20 to 30 per cent. in

severe ones. The mortality is greater in hospitals than in private practice. In the fulminating cases death takes place before a chance for treatment is offered; but in the next grade of cases, characterized by high temperature and severe throat symptoms, a survival of five or six days generally means recovery, unless the supervening complications carry off the patient. Among these, nephritis and glandular swelling passing over to abscess are conspicuous, but even of those so afflicted a majority recover.

Treatment.—After isolation and protection in bed against changes of temperature, the treatment of scarlet fever is, in the main, a symptomatic one, associated with a vigilant nursing that will guard against complications. The patient should be isolated, if possible at the top of the house, and all communication with those of the family who have not had the disease interdicted. The temperature of the room should be uniform, while effective ventilation should be secured. The diet should be liquid as long as the fever persists, and the best of all liquids is milk, though light broths are allowable and an abundance of water.

If the fever is high, say above 103° F. (39.4° C.), cool sponging may be resorted to, but it is to be remembered that high temperature in this disease is usually of short duration and not likely, therefore, to produce the mischief it may cause in long-continued febrile diseases like typhoid fever. Very high temperature, such as 105° F. (40.5° C.), with meningeal symptoms, may require the tub-bath or cold pack, but the temperature of the tub-bath should not be so low as that used in typhoid fever. It is safer to put a patient in a bath at 90° F. (32.2° C.) and gradually reduce the temperature. The warm bath allays the itching of the skin, but this is as well accomplished by inunction with cold cream or sweet oil, and this unguent is important for another purpose as soon as desquamation takes place, to keep the scales from flying about and spreading the contagium. An ice-cap may be applied to the head if the temperature be high, and especially if there are head symptoms. While cool applications are allowable during fever, they are positively contra-indicated in its absence, as they may act in the development of complications of nephritis and otitis.

Fever is best controlled by these measures, but it is desirable to give medicines which tend to the same purpose, especially if they dispose to diuresis as well. Hence, the officinal solution of citrate of potassium or of the acetate of ammonium combined with the spirit of nitric ether, or a couple of drops of aconite with a little flavoring syrup, is useful. Constipation should be guarded against.

The *throat* symptoms require to be treated according to the degree of their severity. Iron and potassium chlorate may be added to the above mixture. If more active local measures are needed, the throat may be sprayed frequently with peroxid of hydrogen (1 to 3) or with a weak bichlorid of mercury solution (1 to 500) or carbolic acid spray (1 to 60). The first is the best. Cold water applications, and even ice to the exterior of the throat, are very comforting to the patient. Very efficient and soothing is a bandage for the throat with pockets opposite to the tonsils, into which pieces of ice are placed and the whole covered with a dry towel; or little india-rubber ice-bags may be similarly used. In adynamic cases stimulants and restorative treatment in general are indicated. Due regard should be had to the tendency of the disease in severe forms to produce degeneration of muscle and the liability of the heart to share in this.

The proper treatment of the throat tends to save the *ear*, but should the

middle ear become involved, the membrane should be watched daily, and if the tension be extreme, perforation practiced, even more than once, if needed. Too little attention has been paid to this complication, and if circumstances permit, an aural surgeon should be called in.

The *prophylaxis* against *nephritis* should be most careful. Whatever may be the immediate cause of the renal involvement, it is certain that cold often becomes its exciting cause. Hence, the patient should be scrupulously guarded against drafts, and, tedious as it may sometimes seem to mother and child, "six weeks in the room" is a precaution which will avert many a case of nephritis. In addition to the milk diet, which is an efficient prophylactic against nephritis, I am in the habit of giving a moderate dose of digitalis, say three to five minims (0.333 to 0.666 gm.), two or three times a day, to aid in maintaining a free movement of the blood through the kidney.

The treatment of complicating nephritis is the treatment of that affection under other circumstances, and the reader is referred to the appropriate section on it.

Serum Treatment.—An important addition to the treatment of scarlet fever has been made by Paul Moser* who suggested the use of antistreptococcic serum, not with a view to combating the disease itself, but the complications which are the result, not of the scarlatinous, but of the streptococcic infection. G. A. Charlton,† of Montreal, and W. R. Hubbert, of Detroit, have reported Moser's treatment with gratifying results. Dr. Charlton says that he employed it in 15 cases, the majority of which would, in his judgment, under ordinary treatment, have terminated fatally, or, at least, have suffered from lingering and troublesome complications. There were thirteen prompt recoveries and two deaths, one case having been in a dying condition and the other complicated by pneumonia when they came under treatment. The frequency of mixed infection is shown by Moser's statement that in 99 cases of scarlet fever streptococci were obtained from blood 63 times. The injections should be made early in the disease. The usual dose is 20 c. c., but in those cases in which the severity of the attack would seem to indicate a larger quantity, the dose may be repeated. After the injection of the serum a rapid subsidence of the pyrexia supervenes, also a corresponding decrease in the pulse rate, with improvement in its tension and rhythm. This seemingly harmless treatment demands a prompt trial for the relief of the dangers of this serious disease.

DIPHThERIA.

SYNONYMS.—*Membranous Croup; Angina maligna; Angina membranacea; Cyanche contagiosa; Diphtheria faucium.*

Definition.—Diphtheria is an acute, contagious, inflammatory disease, caused by inoculation with the Klebs-Loeffler bacillus, and especially characterized by the formation of false membrane and by secondary constitutional infection. It may attack any mucous membrane, and even the skin, but, as usually employed, the term means diphtheritic inflammation of the oral, faucial, nasal, laryngeal, tracheal, or bronchial mucous membrane. The term *diphtheroid* is applied to such membranous inflammations as are not due to the Klebs-Loeffler bacillus.

* "Ueber die Behandlung des Scharlachs mit einem Scharlachsstreptococcenserum," "Wiener klinische Wochenschrift," October 9, 1902.

† "Montreal Medical Journal," October, 1902.

Historical.—Diphtheria has prevailed endemically and epidemically since the days of Hippocrates (406 B. C.). D'Hauvantage, an East Indian physician living at the time of Pythagoras (probably 500 B. C.), described a disease bearing strong resemblance to diphtheria. The first tracheotomy is said to have been performed by Asclepiades, who lived probably more than a century before Christ. Diphtheria was recognized by Aretæus of Cappadocia (100 A. D.), who has left the oldest clear and concise description of this disease, which he called "Syriac ulcer." Galen also described the disease in the latter part of the second century. Paralysis of the soft palate was recognized as one of the consequences of diphtheria in the fourth century by Cœlius Aurelianus, and in the fifth or sixth century by Ætius. During the Middle Ages no accurate descriptions were given, although important epidemics are recorded that no doubt were diphtheria. Ballonius, of Paris, in 1659, gives the earliest recorded reference to the pseudo-membrane of diphtheria.

The disease appeared in this country, in New England, in the seventeenth century. The earliest American literature on the subject appears to be a reference to a number of children that "died from bladders in the windpipe," found in the work of Sibley, of New England, in 1659. An admirable account by Samuel Bond was published in the "Transactions of the American Philosophical Society," at Philadelphia, in 1770. The disease was epidemic for the first time in New York city in 1771. Samuel Bard, in a paper written at that time, described it under the name of "Angina suffocativa," known in common parlance as "sore throat distemper."

We owe the name by which the disease is now generally known to Bretonneau, who applied it in a paper read before the French Academy of Medicine in 1821, wherein he declared, also, that "Angina suffocativa," "Cynanche maligna," "putrid" and other forms of sore throat were one and the same thing.*

The first distinction between catarrhal, croupous, and necrobiotic types of laryngeal diphtheria was made by Virchow in 1847.

Etiology.—The specific organism which by common consent at the present day is the cause of diphtheria is the so-called Klebs-Loeffler bacillus, a bacillus, non-motile, slightly bent, with rounded ends, 2.5 to 3 microns † in length, and from 0.5 to 0.8 micron in thickness. It stains readily by Loeffler's methylene alkaline blue in cover-glass preparations and in sections. Its cultures in blood-serum are small, round, grayish-white colonies that are characteristic. These, with the clubbed ends of the bacillus and clear spaces in its interior, giving it an appearance as if broken, suffice for its recognition. It grows on all the usual culture-media, but ceases to grow at a temperature below 20° C. (68° F.). If inoculation cultures are practiced on the lower animals, the nature of the virus is declared by the exudation, the bacilli, the swelling of adjacent lymphatic glands, and the invariably fatal results of such inoculation. The bacillus produces in its growth a potent toxic substance, or toxalbumin, the absorption of which from the seat of local infection causes the general symptoms of the disease, which are therefore due to this toxin and not to an invasion of the blood by the organism producing it. The toxin is an albuminous substance, but its composition is unknown. When injected into animals, it produces paralysis, nephritis, and albuminuria. Roux and Yersin were the first to show, in 1888, the pathogenic property of cultures that had been filtered through porcelain.

The successful implantation of the bacillus of diphtheria is, however, dependent on various circumstances. Certain temporary states of the individual doubtless favor it, while others retard it. While general weakness or feeble resisting power may be one of these conditions it is likely also that purely local states, such as uncleanness of the mouth, teeth, and fauces, as well as chronic inflammatory conditions, may act as predisposing causes. Enlarged tonsils and nasopharyngeal catarrh predispose. It has been shown that there are different degrees of virulence in the contagious organism itself.

The bacillus of diphtheria is associated with other pathogenic bacteria,

* The history of diphtheria is one of the most interesting chapters in medicine, and is more fully considered in the classic paper of Abraham Jacobi in the "System of Medicine by American Authors," Philadelphia, 1885.

† A micron is a $\frac{1}{1000}$ millimeter, or $\frac{1}{25400}$ inch.

such as *streptococcus pyogenes* and *staphylococcus albus* and *aureus*, *micrococcus lanccolatus*, and *bacillus coli communis*, which are probably responsible for suppurative processes often associated, as well as for certain deep-seated inflammatory conditions and certain forms of pseudo-diphtheria, which often complicate the disease and are sometimes mistaken for it. The streptococcus is probably the most active.

It was formerly believed that defective drainage, and to a less extent also the upturning of soil, were conditions favoring the production of diphtheria, but such views are not sustained by modern studies. On the other hand, army statistics seem to show that foul air causes simple follicular sore throat, which in seasons of epidemics makes an excellent nidus for the growth of the diphtheria bacillus. The contagion is communicated, as a rule, through the air and not by fluids ingested, although epidemics have been traced to milk, in which the bacillus multiplies. In the vast majority of instances the source of the contagion is the throat or nose of another individual affected, whence it is propelled by acts of coughing or expectoration. Hence it happens that the physician and nurse are not infrequently infected. Perhaps in this disease, more than any other, excepting typhus, are doctors and nurses the victims of contagion. Much may, however, be done to secure protection by caution during such ministrations, as by keeping the mouth closed and carefully cleansing the hands after contact. The practice of examining throats through a plate of clear glass is a further protection against inoculation of the examiner. The contagion is less tenacious than that of scarlet fever, but is still highly so, having been found to live on blood-serum for one hundred and fifty-five days; dried on silk threads, one hundred and seventy-two days; and in gelatin, for eighteen months. It has been found on a child's toy that had been kept in a dark place for five months, and in the hair of nurses. It resides also in the healthy throats of immune persons, in simple catarrhal angina without membrane, and in simple lacunar tonsillitis; whence it is plain how the disease may arise without apparent cause in certain sporadic cases.

It is believed by some that diphtheria affects the lower animals, especially the cat, and may be transmitted from them to children. It is said, also, that such an affection attacks calves and heifers, and is from them communicable to man.

The disease is much more common in children than in adults, though no age is exempt. It is rare in very young children, and more girls are attacked than boys. Abraham Jacobi, whose experience has been very large, has seen only three cases in the newly born. Several cases in children about six months old have come under my notice. Epidemics vary in severity, and winter is the season in which the disease is most prevalent. While crowding in cities favors it, it is often widespread and virulent in the country.

Morbid Anatomy.—The morbid anatomy of diphtheria consists, on the one hand, in the presence of the false membrane and of the more ordinary phenomena of inflammation, most of which latter disappear after death; in the deep-seated ulcerative processes that sometimes result; and in the results of the complications and sequelæ to be considered later. The paralysees do not furnish palpable morbid products.

Under morbid anatomy the constitution of the false membrane is suitably considered. At its first appearance it is yellowish-white, but later may assume a grayish hue. Whether superimposed on a mucous membrane or

set into it as in a frame, depends much upon the character of the epithelium with which the surface is normally covered. To squamous epithelium the membrane is more deeply and thoroughly attached; to columnar epithelium, such as lines the larynx or bronchi, it is more loosely adherent; but in both situations it tends to become looser with the lapse of time.

The membrane itself is to-day considered a product of what is known as *coagulation-necrosis*, our knowledge of which is based on the studies of Wagner, Weigert, and especially of Oertel. The mechanism of its production is as follows: The diphtheritic poison, probably admixed with fibrin from the blood, infiltrates the wandered-out leukocytes and the epithelial cells of the part, especially the more superficial, causing first their death and then a hyaline transformation, and simultaneously coagulation. The resultant is a plate of necrotic tissue and coagulated fibrin. Hence the word "coagulation-necrosis." The membrane presents, also, a laminated structure, probably due to the involvement of successive layers of tissue and wandering cells. If forcibly separated, especially when recent, it is apt to leave a bleeding surface, on which new membrane is generally promptly deposited. The process proceeds from without inward, and, though usually superficial, may extend more deeply, invading lymphatic glands and adjacent tissue, producing foci of necrosis, which may be extensive. Blood-vessels may also be invaded, especially capillaries. Bacilli are everywhere present, but they do not directly produce the mischief. It is caused by the toxin they generate. The same results may be produced experimentally.

Inflammatory membrane of this kind is not the product of the toxin of diphtheria only. Any intense irritant is capable of producing it. Such are corrosive poisons like nitric acid and ammonia, although the necrotic product is here partly the result of the direct action of the agent itself on the tissue. Similar in its effect is the organism of scarlet fever, whatever it may be, which often produces a pseudo-membranous angina difficult to distinguish in its coarser characters from that of diphtheria, but in which is not, as a rule, found the Klebs-Loeffler bacillus. In this membrane have been found streptococci, staphylococci, and diplococci. The micrococcus of sputum-septicemia, and the *oidium albicans* may produce such false membrane. The streptococcus is probably the most frequent cause. Such false membranes may be called diphtheroid.

Symptoms.—The *period of incubation* varies from two days to twelve, seldom exceeding one week.

According to what may be the primary or principal seat of invasion we may speak of the *pharyngeal*, *laryngeal*, and *nasal* forms of diphtheria.

In the pharyngeal variety, *fever* and *sore throat* appear simultaneously, sometimes preceded by a chill or chilliness. Both increase rapidly. There may be aching or a sense of weariness. More rarely a *convulsion* ushers in the attack. At times at the beginning, at others on the second or third day, an *erythematous eruption* more or less extensive appears on the skin and may lead to the diagnosis of scarlet fever. Usually, as soon as attention is called to the throat, white patches are found on one or both tonsils, which spread with varying rapidity. *It is this spread from the original focus by which the disease is especially characterized as something distinct from follicular tonsillitis.* Commonly, the extension is anterior, over the anterior half-arches to the uvula, and to the palate or up into the nasal passages, or both. With the invasion of the uvula and palate, commonly reached about the fourth day, the diagnosis becomes certain, even without the bacterio-

logical examination. More serious is the extension backward into the larynx, producing croup.

The *temperature* rises to 103° or 104° F. (39.4° or 40° C.), but is not characterized by extreme or persistent elevation. The *pulse*, which ranges from 120 to 140, is never very full and strong, but tends early to smallness and weakness. *Delirium* is rarely present. *Deglutition* becomes more and more painful, and is increased by *external glandular swelling*, involving the lymphatic and salivary glands, although this swelling is not invariably present. As the *nasal passages* become involved, breathing becomes more and more obstructed, until, finally, it is possible through the mouth only. The *Eustachian tube*, *middle ear*, and even the *antra* may be invaded. So, also, there may be *diphtheritic conjunctivitis*, and even keratitis, and, though rarely indeed, dermatitis. Should there be, however, excoriations or wounds, these may be invaded by the diphtheritic pseudo-membrane. Such false membrane may, however, be due to the streptococcus, which requires a bacteriological examination for its recognition.

As intimated under the head of morbid anatomy, the *ulcerative process* may extend much more deeply, producing destruction of tissue and even gangrene, resulting, as in scarlet fever, in a fatal erosion of blood-vessels. Usually, the membrane gradually disappears from the fauces as convalescence is established, or is coughed up if deeper in the respiratory passages. Sometimes, on the other hand, it remains on the tonsils for some days after all constitutional disturbance has disappeared.

If the inflammation and membrane formation extend downward, *laryngeal cough* and the signs of laryngeal obstruction become superadded—in a word, the symptoms of *pseudo-membranous croup* supervene. Or if the process begins in the larynx—*primary laryngeal diphtheria*—we have croup at the outset, which differs from spasmodic croup in being less sudden in its onset. The seriousness of the disease is greatly aggravated by the possibility of complete obstruction and suffocation unless averted by operative interference. Not the larynx alone, but the trachea and bronchi may be invaded by false membrane. While the onset is slower than that of pharyngeal diphtheria, the course is more rapid. To the phenomena of congestion and membrane formation with resulting obstruction are added those of spasm, which brings on at intervals the alarming paroxysms that add to the terrors of this horrible affection.

Nasal diphtheria, in which the nares are especially invaded by the false membrane, requires special allusion. It is more apt to succeed upon acute nasal catarrh with little secretion than on chronic catarrh. The effect of the invasion is to increase any previous discharge, which is also rendered acrid and irritating. In this form glandular swelling of the deep faucial glands at the angle of the jaw is particularly prone to occur, probably on account of the richness of this locality in lymphatics, and persists as induration, while a chronic pharyngeal and nasal catarrh may persist a long time after disappearance of the membrane. Jacobi, who also especially emphasized the diagnostic value of this peculiar glandular swelling, called attention to the fact that this form of catarrh is not only liable to be a focus of fresh attacks, but may also be a source of spread to others. Suppuration in these enlarged glands rarely occurs.

In three to five days after the onset, if the case is one of ordinary severity, the phenomena of *constitutional infection* make their appearance in extreme *adynamia*, *febleness of pulse* and *heart-beat*, while a sense of

intense weariness is complained of. From this time a new period of danger begins, the danger of death from heart failure. This is a distinct and separate cause from heart paralysis due to neuritis of cardiac nerves. At times in diphtheria, as in scarlet fever, the signs of constitutional poisoning appear at the outset, and the patient is struck down as by a blow, but this is less common than in scarlet fever. In such cases the temperature may not rise, and may even be subnormal. Constitutional poisoning is not so prone to take place in primary laryngeal croup as in secondary croup. This lesser tendency to constitutional poisoning together with the more gradual onset, the spasm, the slighter contagion, the shorter duration, and more serious mortality, constitute the chief clinical features of the laryngeal variety.

Complications and Sequelæ.—The most frequent complication of diphtheria is *nephritis*, which pursues a course somewhat similar to the nephritis of scarlet fever, but is less frequently accompanied by dropsy, and generally terminates more favorably. On the other hand, albuminuria is present in almost every severe case. There may be the other signs of nephritis—viz., blood-casts, epithelial casts, scanty and even suppressed urine. *Capillary bronchitis* and *bronchopneumonia* are serious complications, especially if the results of inflammation of the virulently laden membrane. Endocarditis and arthritis sometimes occur.

The most important sequel of diphtheria is *paralysis*. This is now generally regarded as the result of a *toxic neuritis*. It may come on as early as the seventh or eighth day, or as late as the second and third week, when convalescence is apparently established. It is quite as likely to follow mild cases as severer ones. It may even follow wound-diphtheria. It most frequently affects the *palate*, producing nasal speech and permitting the passage of fluids into the posterior nares and through the nose. There is simultaneous *anesthesia of the pharyngeal mucous membrane*, destroying reflex excitability. Next in frequency of involvement are the muscles of *deglutition*; more rarely, the *eye muscles*, especially those of accommodation, which is thereby rendered defective. There may be also ptosis and strabismus, or paralyzes of the distribution of the facial nerves. Still more rarely the nerves of the lower extremities are involved, producing paralysis, partial recovery from which leaves lameness that may last through life. Generally, however, recovery takes place in the order of involvement, usually in two or three weeks. Sometimes there are *ataxic symptoms*, with *loss* of the tendon *reflexes*, and no involvement of sensation.

The most serious of the local palsies is that of the *heart*, due to neuritis of the cardiac nerves. In this there may be bradycardia and tachycardia, but the most frequent result is the sudden cessation of the heart's action, and this tragic termination may take place during convalescence. Indeed, the event is more frequent during convalescence, and is often as late as the sixth or seventh week. At other times the phenomena of heart failure are more slow in their development. The pulse may become weak and rapid, or more rarely become slow, while the extremities become cold, the temperature falls, and there supervene in a few hours all the signs of collapse. A most striking instance of bradycardia in diphtheria was met by Baumgarten, wherein, toward the close, the pulse fell to 25, though very regular.

Diagnosis.—The only two conditions with which diphtheria is liable to be confounded are, first, the different forms of *diphtheroid faucitis*, including follicular tonsillitis, and, the faucitis of scarlet fever. The difficulty in deciding between the former condition and diphtheria at the outset is some-

times extremely great, and time or the bacteriological investigation may alone settle it. The primary fever, constitutional disturbance, and dysphagia are often equally as great in follicular tonsillitis due to streptococcus or some other cause of infection. As a rule, however, the follicular exudate remains limited in size—it does not spread, and in the second or third twenty-four hours is apt to drop out, leaving a clean-cut ulcer that heals rapidly, while the constitutional symptoms disappear with equal rapidity. In the form of follicular tonsillitis attended by multiple white spots on the tonsils the local resemblance to diphtheria is even greater, but the white spots remain isolated, while those of diphtheria spread.

Sometimes, however, the mass of desquamated epithelium, fibrin, and fungous filaments, which make up the contents of the follicles in follicular angina extend outside of the follicles and over the surface of the tonsils. Then it becomes more difficult to decide. It does not, however, pass the boundary of the tonsils. The follicular fungi are said to stain bluish-red with an iodopotassic iodine solution. Further certainty is secured by making cultures from the membrane, a small portion being removed by the sterilized platinum loop or cotton swab, and planted in gelatinized blood-serum. In the course of twenty-four hours characteristic colonies will develop, and the microscope will confirm the diagnosis.

From *scarlet fever*, diphtheria is usually easily distinguished by the absence of eruption, although this aid is wanting in those few cases of scarlet fever in which there is no eruption, and in those of diphtheria where there is an erythematous redness. Under these circumstances the distinction becomes more difficult if the throat symptoms be similar, as they sometimes are. The prevalence of an epidemic of one or the other disease aids in the decision. Later on, the desquamation that takes place in scarlet fever, but not in diphtheria, also settles the question.

Diagnosis is sometimes delayed or the disease entirely overlooked by concealment of the membrane in localities not easily open to examination, as in the nasal chambers. Hence, in all obscure cases these should be examined. Indeed, it is not impossible that diphtheria may exist without membrane, as evidenced by prompt recovery after the use of antitoxin in certain obscure throat cases with continued adynamia and fever.

The larger cities in the United States now offer, through their health bureaus, to make bacteriological examinations for physicians in all cases of possible diphtheria. Outfits are left at stations. They consist of a box containing a tube of blood-serum and another containing a sterilized swab. The following directions are issued by the Philadelphia Board of Health:

“Inoculations should be made by rubbing the cotton swab attached to the end of the wire contained in the test-tube gently, but freely, against any visible exudate, and then drawing it over the surface of the culture-medium without breaking the surface of the latter. The swab should then be replaced in the tube from which it was taken, and both tubes be replugged and put back into the box. Return the box to the station from which it was obtained as soon as possible, or bring it directly to the laboratory. The tubes will be collected every afternoon, examined the following morning, and reports will be mailed by one o'clock P. M. The attending physician can obtain information, however, by telephoning directly to the laboratory after that hour.”

Prognosis.—The introduction of the serum treatment for diphtheria,

which may be dated April, 1893, when the first 30 cases treated by Behring's normal serum were reported,* marks an era prior and subsequent to which the prognosis of diphtheria presents very different aspects. Even prior to 1893, while the prognosis was so unfavorable as to justify a wholesome dread of the disease the world over, many moderately severe and most mild cases got well. Allowing for the great variation in the percentage of fatal cases in different epidemics, and especially at different ages, the very careful and reliable studies of Professor William H. Welch,† of Johns Hopkins Hospital, make it safe to put such mortality at a minimum of 40 per cent. Where the larynx was involved, it amounted to almost 100 per cent. Of the remaining non-laryngeal cases probably one-third died. Since the introduction of the antitoxin treatment the studies of the same observer (Welch) show a reduction in mortality of between 50 and 60 per cent. This improvement affects all classes of cases, including those operated upon as well. As near as it may be possible to put it, the mortality since the introduction of antitoxin has been from 8 to 25 per cent. This is attested from many sources. For example, in the report of collective investigation by the American Pediatric Society we have the following: "Formerly, 27 per cent. approximately represented the recoveries, while now 27 per cent. represents the rate of mortality"; also "Formerly, only 10 per cent. of laryngeal cases did not require operation, while now with antitoxin treatment 17 per cent. do not require this procedure." Finally, the most remarkable results are shown in the "Bulletin of the Department of Health," city of Chicago, for February, 1899, which reports that out of 4071 cases of *bacterially verified* diphtheria, 3705 recovered and 276 died, giving a mortality rate of but 6.77 per cent. In New York City for 1899 there were 8240 cases reported with a mortality of 1087, or 13 per cent.

During thirteen months ending October, 1896, 1972 patients were treated with antitoxin at the Boston City Hospital, and of this number post-diphtheritic paralysis occurred in 5.8 per cent., which percentage is smaller than that of cases not treated with antitoxin. A fair ratio of the causes of death in 25 fatal cases prior to the use of antitoxin was given in a paper by William P. Munn‡ as follows: from septic intoxication 8, laryngeal stenosis 7, cardiac paralysis 6, hemorrhage from the bowels 1, nephritis 1, unknown 2; total 25. Thus the chief causes of death are adynamia, laryngeal obstruction, heart paralysis, or suffocation from paralysis of deglutition; more rarely, nephritis and bronchopneumonia. Hemorrhage from an eroded blood-vessel is a possible cause of death. Morse analyzed 366 deaths occurring in 1972 consecutive cases treated since 1895 in the Boston City Hospital, and found the mortality only 18.5 per cent. Seventy of these cases died on the day of admission, and 38 on the following day; in other words, 100 were moribund on admission. The following are the causes of death: sepsis, 107; bronchopneumonia, 91; cardiac complications, 52; exhaustion, 13; tuberculosis, 1; empyema, 1; typhoid fever, 1; moribund when admitted, 100; total, 366.

Under the use of antitoxin the average duration of an ordinary case may be put down at about five days and of a very bad case ten days. It is impor-

* The prior trials of immune serum in the treatment of human diphtheria, made in v. Bergmann's clinic in Berlin in 1891, and by Hensch and Huebner in Berlin in 1892, were tentative and made with weak serum and in insufficient doses.

† "The Treatment of Diphtheria by Antitoxin." Reprint of paper read before the Association of American Physicians, May 31, 1895, and published in the "Transactions" for that year.

‡ "Diphtheria: a Clinical Study." "Medical News," Philadelphia, March 25, 1893.

tant to remember, however, that actively growing bacilli can be cultivated from the throat of cases treated early with antitoxin, two weeks after the membrane has disappeared.

Treatment.—In the management of every case of diphtheria there are two principal indications: first, to combat the toxin and thereby neutralize constitutional infection; second, to co-operate with this object by suitable supporting treatment.

I. To combat the toxin and to prevent constitutional infection. This is accomplished (*a*) by serum therapy, that is, by antitoxin; (*b*) by local antiseptic measures.

(*a*) *Antitoxin.*—The treatment of diphtheria by antitoxin should be associated with the general and local treatment to be described. It is based on the facts that animals may be made immune to diphtheria by the injection of diphtheria toxin, and that the serum from such animals is antitoxic to the toxin of diphtheria. This was shown by Behring in 1891, after some preliminary experiments had been made by Fränkel in the same year. In 1892 Behring and Wernicke employed this method successfully in immunizing sheep, and also ascertained the second important fact mentioned that blood-serum from an immune animal could be used with success in arresting diphtheritic infection in susceptible animals. To this was added the further important fact that *a smaller amount of serum is required to produce immunity than is necessary for the cure of an animal already infected. If the injection be made immediately after infection, from one and a half to twice as much is required; eight hours after, three times as much, and twenty-four to thirty-six hours after infection the dose required is eight times the immunizing dose.*

In obtaining a uniform standard of strength Behring produced first his *normal therapeutic serum*, which when injected into guinea-pigs, in the proportion of 1 to 5000 of body weight, saves the animal from the fatal effects of ten times the minimum dose of a two-day-old culture fatal to a control animal not thus treated. *One cubic centimeter of this normal serum he calls an antitoxin unit.* The serum prepared by this method he labeled three strengths: No. 1 is 60 times the strength of the normal serum; No. 2, 100 times as strong; and No. 3, 140 times as strong. Behring claims that 10 c. c. of his No. 1 serum is sufficient to arrest the progress of the disease in a child under ten years, and effect a cure if given within two or three days after the onset of the attack. This older method of Behring has been replaced by other modern methods.*

One of the objections to the serum treatment at first was the necessarily large bulk of the injection. This has, however, been reduced by increasing the strength of the serum, so that the dose now injected gives no more discomfort than a hypodermic injection of morphin. Reliable preparations are now made in this country, notably by the Mulford Company, in Philadelphia, and by Parke, Davis & Co., in Detroit, Mich., and in some cities by the official authorities under direction of the city board of health. Two strengths of serum are made by these firms, the "standard" and "concentrated" serum. The latter is more bulky, 1000 units being

* The method of the Mulford Co. is briefly as follows:
Determine by trial on a large number of guinea pigs the smallest surely fatal dose of toxin. Take other guinea pigs and determine the smallest fraction of a cubic centimeter of serum that will protect the guinea pig against 100 times the fatal dose of toxin. This fraction of a cubic centimeter will then contain one unit, and there are in one cubic centimeter as many units as the fraction will go into the whole cubic centimeter. Thus if $\frac{1}{250}$ of 1 c. c. is the smallest quantity that will protect, then the serum has 250 units per c. c.

represented by 5 to 10 c. c., while 1000 units of the concentrated are represented by 2 c. c.

Technique of the Administration of Antitoxin.—Antitoxin should be administered *at once* if there is a reasonable probability of the presence of diphtheria, without waiting for the bacteriological diagnosis. Antitoxin does no harm where the disease is not diphtheria, and delay in a true case may be fatal.

The beginning dose is 1000 *units* for ordinary pharyngeal diphtheria. The “concentrated” form is preferred on account of its small bulk, which gives no more pain than a hypodermic injection of morphin. If, for any reason, the concentrated form cannot be procured, the “standard” may be used, which is cheaper and just as efficacious, but gives much more pain because of its greater bulk. One thousand units of this is indicated also.

The bulk of 1000 units, concentrated form, is 2 c. c.; 1000 units, standard form, 4 c. c.

A large hypodermic syringe is used for the administration. The syringe must be made sterile by boiling for five minutes just before being used. Always test the syringe with water before filling with serum. *After* the administration the syringe should be washed out with clean cold water.

The injection is given in the back just below the scapula or in the flank or buttock, the skin being cleaned with soap and water followed by alcohol. It is pinched up and the injection made immediately beneath it. If the smaller bulk be used, it can be injected quickly. If the larger bulk be used, inject slowly in order to avoid injury to the underlying tissues by too rapid stretching. Immediately after the injection there is an occasional rise of temperature, which need give no concern.

In favorable cases, after twenty-four hours have passed, the temperature will not have risen; the pulse will be slower; the membrane will *not* have spread; the mucous membrane at the edge of the exudation will be bright red in color. There will be a feeling of diminished discomfort and revival of spirits. These are favorable signs, and a second dose need *not* be administered. A second dose is administered after twenty-four hours if the temperature has risen, if the membrane is spreading, and if the general condition of the patient is not so good as at the previous injection. As might be expected, improvement is more rapid in mild cases.

In laryngeal diphtheria (membranous croup) the initial dose is 2000 units. The same beginning dose is also given in bad cases of the pharyngeal or nasal form that have lasted some days. In these forms a second dose should also be administered, if there is not improvement in *twelve* hours.

For Immunization.—For producing immunity to those subject to infection from diphtheria, immunizing doses should be administered. These range from 200 to 500 units, according to the age of the person to be protected. Infants and very young children are easily protected by the smaller dose. Adults, especially those in attendance upon the sick, should receive the larger dose. Persons who have been exposed and probably are already infected should receive 500 units. The throat irritation so common in those who are attending diphtheria is said to have yielded promptly to a dose of 500 units. If suspicious symptoms have appeared, not less than 1000 units should be given.

Immunization cannot be too strongly insisted upon. The protection afforded by one dose will last for at least three or four weeks, at most

not more than eight or ten weeks; within which time, with proper means of disinfection, the source of infection should be eliminated.

Behring and others declare that the diphtheria antitoxin has no injurious effect upon animals in the largest dose in which it has been employed, and that, aside from its antitoxic powers, its properties are entirely negative, as far as human beings are concerned. This is essentially true; yet there is evidence to the contrary, notably, a fatal case reported in the "Journal of the American Medical Association," April 4, 1896, that of a healthy boy, five years old, who received an injection of Behring's fresh serum as a prophylactic and died within five minutes: also another case, in Berlin, referred to in the "Medical News," April 18, 1896, page 443. The daughter of a friend of the author died suddenly in Switzerland after receiving an injection of antitoxin.

(b) *Antiseptic Local Treatment to Prevent Constitutional Infection.*—Germicides and disinfectants are best applied, when possible, by the spraying apparatus at intervals of an hour, or, at most, every two hours. If the spraying apparatus cannot be used, as is often the case with children, a swab of cotton wool or a soft sponge may be employed. The most satisfactory solution in my hands for this purpose has been equal parts of *peroxid of hydrogen* and *Dobell's solution*. The spraying should be continued five minutes, if possible. *Bichlorid of mercury* is also a suitable solution for spraying, of strengths of 1 to 4000, or even, in extreme cases, 1 to 2000. The most efficient bichlorid solution is that with tartaric acid 1 to 500,* with which the throat may be swabbed once in six hours, or even, in severe cases, once in three. The objection to the corrosive sublimate solution is its extremely unpleasant taste. *Carbolic acid* may also be used in 2 1-2 to 3 per cent. solution, in equal parts of glycerin and water. The stronger solutions are better applied by a swab than by the spray apparatus, while with children it is often impossible to use the spray. Solutions of albumin solvents are also highly recommended by some, such as *trypsin* and *papoid*, in the strength of 30 grains to 1 ounce (2 gm. to 30 c. c.) or *lactic acid* in the same proportion. *Salicylic acid*, 1 to 300; *thymol*, 1 to 2000; *chlorin water*; *boric acid* in saturated solution; saturated solution of *iodoform* in ether or 5 per cent. suspended in equal parts of glycerin and water, are all useful local applications. Loeffler's *toluol solution* is highly praised. It is composed of menthol, 10 gm. dissolved in enough toluol to make 36 c. c.; sesquichlorid of iron, 4 c. c. and absolute alcohol, 60 c. c. Still another solution is tincture of the perchlorid of iron, 1 1-2 drams (6 gm.): glycerin and water, each 1 ounce (30 c. c.): carbolic acid, 15 to 20 minims (1 to 1.3 c. c.). Where there is laryngeal diphtheria, the patient should breathe an atmosphere saturated with the vapor of slaking lime. The comfort derived from such breathing is often very great.

While iron and the chlorate of potash have lost some of their former reputation, they are still, in my judgment, indispensable, and I always combine them with any other treatment I may care to use. As held by Jacobi, they are, at least, useful in the concurrent pharyngitis and stomatitis that invariably attend the disease. The chlorate of potash in saturated solution may be used as a simple mouth-wash. Gargling is an ineffectual method of reaching the throat, and has given place to spraying. Still it may be

* A tablet consisting of 3.75 grains (0.25 gm.) bichlorid of mercury to 10.25 grains (1.25 gm.) of tartaric acid, dissolved in 4 ounces (120 c. c.) of water, makes a 1 to 500 solution.

used with advantage by adults. Much depends upon a certain facility in using it, which may be cultivated.

Jacobi recommends that in children too young to use the gargle the local effect of the chlorate of potash be secured by frequent administration of small doses. Thus, regarding 1 1-2 to 2 drams (6 to 8 gm.) as a suitable twenty-four hours' quantity for an adult, 30 grains (2 gm.) for a child two or three years, and 20 grains (1.33 gm.) for a baby a year old, he prefers the whole amount to be given in 50 or 60 doses rather than 8 or 10, giving the weaker dose every hour or half-hour, or every fifteen or twenty minutes, being careful to give no water immediately afterward, for obvious reasons. But I have seen the thing overdone: I have seen a little child, exhausted for want of sleep, aroused every fifteen minutes for the administration of medicine, when what it wanted was sleep more than medicine.

II. The second object includes measures which also have for their purpose, first, checking the spread of the membrane, its loosening and solution, and, second, maintaining the strength of the patient against the depressing action of the absorbed toxin. (a) The former is accomplished by the preparations of mercury. Of these, I prefer the bichlorid of mercury in doses of 1.48 grain (0.0027 gm.) to 1.12 grain (0.005 gm.) for an adult, in conjunction with tincture of the chlorid of iron and the chlorate of potassium, every two hours, taken freely diluted. The former dose makes 1.4 grain (0.0162 gm.) of the bichlorid in twenty-four hours, but as much as one-half (0.032 gm.) may be given in that period. These doses are given to adults, and they need not be much reduced for children. There need be little fear of poisonous effects from the bichlorid, as bowel irritation, pain, and loose movements give a warning before any more serious consequences supervene. When these symptoms appear, the bichlorid should be discontinued or the dose decidedly diminished. The calomel treatment is preferred by some. The drug is given in hourly doses of 1.6 or 1.8 grain (0.016 or 0.008 gm.) until spawn-like stools are produced. Both remedies are supposed to have the effect of loosening the membrane.

(b) Iron is also useful in supporting the strength of the patient. For this purpose quinin is indispensable in doses of 10 to 24 grains (0.65 to 1.5 gm.) in the twenty-four hours. Stimulating, nourishing, and easily assimilated food is necessary. Milk is to be preferred to all else, fortified with full doses of whisky or brandy, 2 drams to 1 ounce (8 to 30 c. c.), every two hours, being required in all cases of severity, and proportional doses for children. The milk may, of course, be alternated with nutritious animal broths or beef-peptonoids. In extreme cases of difficult deglutition nutrient enemas may be useful, but nourishment by the stomach-tube, if possible, is more efficient. For enemas, peptonized milk is the most suitable. To this brandy or whisky may be added, if needed. Rectal alimentation has sometimes to be discontinued because the enema is made too large and is too frequently administered. Once in four hours is often enough, and 4 ounces at a time are as much as the rectum will commonly bear. Smaller quantities should be used for children.

Treatment Demanded by Special Forms.—Where *laryngeal obstruction* is imminent, intubation or tracheotomy should be performed. Lives have been saved by both of these operations. Intubation may precede tracheotomy, as its use does not preclude the more serious operation at a later date, if the obstruction increases. Such cases should breathe an atmosphere charged with the vapor of slaking lime.

In the *nasal* variety of *diphtheria* special means must be employed to disinfect and cleanse the nasal passages. The solutions recommended to spray the throat may be used for such cleansing. Gentle injections into the nostril may be more efficient than the spray, precaution being taken to keep the mouth open, by which the entrance of fluid into the Eustachian tube is guarded against. The injections should be continued until the fluid has free exit either by the other nostril or through the mouth. Jacobi has seen cases where he has been compelled to bore a passage with a silver probe through a mass of membrane filling the nasal cavities, and then apply carbolic acid to remove the denser portions before injecting. He recommends that when about to bring the injection to a close, the nasal cavities should be pressed together for an instant with the fingers, as in this way the fluid is forced backward into the pharynx and swallowed or ejected through the mouth, thus washing both at the same time.

The Treatment of Complications and Sequelæ.—Complications are treated as the same conditions under other circumstances, and the paralysis so frequently succeeding upon diphtheria alone requires special allusion. The prognosis is, on the whole, good, and time, under favorable circumstances, mainly effects the cure, and during this the most important measures are those that save the patient from accident. Thus if there is paralysis of the muscles of deglutition, liquid food only should be used, and it may be necessary to nourish for a time by the rectum or by means of the stomach-tube. So, too, undue exertion should be avoided. Electricity and tonics, especially strychnin, are indicated. The former is applied to wasting muscles, and may be advantageously associated with massage. Strychnin should be given in full doses, ascending gradually to 1-20 grain (0.003 gm.) three and four times a day, with appropriate reduction for children. Iron and quinin should also be given.

The electrical treatment for paralysis of the pharyngeal muscles is applied in the following manner: An electrode is placed at the back of the neck and a very small electrode is touched to the velum palati, and a rapidly interrupted faradic current of moderate strength applied. Galvanism may be similarly used. A specially constructed electrode is also applied to the throat.

Prophylaxis Against Diphtheria.—Most important are the precautions necessary to prevent a spread of the disease. To this end the patient should be isolated, all carpets and unnecessary furniture and hangings should be removed from the room, and all utensils used in treatment should be kept apart and separate for the patient's own use. Spoons and tongue depressors should be kept in carbolic acid solution, or, better, thrown into water kept boiling. All bed linen and clothing removed from the patient should be boiled, being immersed in water before removal from the room. Mattresses, pillows, and woolen garments too good to be destroyed should be exposed to superheated steam in establishments provided for the purpose in the cities; or they may be disinfected at the same time with the apartment occupied by the patient. They should be opened and suspended in this apartment, of which all the doors and windows must be closed tightly and the room fumigated with formaldehyd gas, of 2 to 4 per cent. volume strength, for not less than twelve hours. Suitable lamps are provided for this purpose. If formaldehyd is not available, sulphur may be used. The sulphur, in the amount of 2 pounds to every 10 feet (2 kilos to every 2.5 meters)

square, should be placed in iron pans and these supported by bricks in washtubs containing a little water. The sulphur is then ignited by glowing coals or by burning alcohol. The room should be kept closed for twenty-four hours. After this fumigation the articles of clothing should be hung out in the open air for several hours, and the doors and woodwork washed well with a solution of corrosive sublimate, 1 to 1000, while the walls should be wiped down with a similar solution.

Finally, physicians and nurses in attendance on the patient should carefully wash their hands before leaving the room, first in soap and water, and finally rinse them in corrosive sublimate solution, 1 to 1000. Nurses in constant attendance should wear an overdress of washable material, which should be slipped off before leaving the room, and the physician while in the room should be similarly covered and should treat his hands as described.

As the bacillus has been found to multiply in milk, it is safer to use sterilized milk during an epidemic.

The convalescent patient should also be kept isolated until thoroughly disinfected. This is accomplished by giving first a hot water and soap bath, then washing the body of the patient with a solution of bichlorid of mercury, 1 to 2000, or 2 per cent. solution of carbolic acid, or, what is more agreeable, 25 to 50 per cent. alcohol. This should be done two or three days in succession. The hair should be cut or similarly washed with these solutions. The regulations of the Board of Health of Philadelphia do not permit the children of a family in which diphtheria has been present to return to school until thirty days after the Board's physician has declared the patient's recovery.

SMALLPOX.

SYNONYM.—*Variola*.

Definition.—Smallpox is an acute contagious disease especially characterized by an eruption which passes through the successive stages of papule, vesicle, pustule, desiccation, and desquamation.

Historical.—Smallpox was first accurately described by Rhazes, an Arabian physician, in the ninth century of the Christian era, and distinguished by him from measles; but it is believed to be the same as the *pesta magna* described by Galen (A. D. 130-200.) It prevailed also in China many centuries before the Christian era. It is known to have prevailed in the sixth century and again during the Crusades. The disease is believed to have been introduced into America by the Spaniards, having first appeared most fatally in Mexico in 1520, and in Massachusetts in 1633. In evidence of the virulence of the disease it may be mentioned that in Iceland in 1707, 18,000 perished out of a population of 50,000. In Mexico three and a half millions were suddenly smitten. Sydenham's classic description was made in the seventeenth century.

The immunity secured by a previous attack suggested to Lady Mary Wortley Montagu the idea of inoculation for the purpose of protection, the practice of which was introduced in England in 1718. Long before this the Brahmans had discovered that the inoculation of smallpox produced the true disease in a milder form, so that the malady proved fatal only to 1 in 100, or under most favorable circumstances, 1 in 300. It was, moreover, practiced for centuries in China and other Asiatic countries. The effect of inoculation was, however, to spread the disease, though in a milder form, and it was not until the discovery of vaccination by Jenner in 1798, that control over the disease was obtained.

In 1796 Juncker wrote that 400,000 lives were lost yearly in Europe by smallpox. In 1803 King Frederick William of Prussia, in an edict, stated that 40,000 die annually in Prussia of the disease. As already mentioned, inoculation of smallpox was intro-

duced into England, in 1718, by Lady Mary Wortley Montagu, the wife of the British Ambassador to Turkey; into Germany in 1721, but was not popular until 1740. The peasantry in various parts of the world, particularly in England, believed that sores on the hands of persons who milked cows affected with cowpox conferred immunity from the disease. It is said that a Dorsetshire English farmer successfully vaccinated his wife and two sons as early as 1774 from a cowpock on himself. In 1791 Plett, a Holstein schoolmaster, vaccinated three children, in one case on the finger-tips, which caused inflammation of the arm and deterred him from repeating the experiment. These three children escaped the epidemic in 1794. Edward Jenner, while a student, learned of the traditions on this subject and mentioned them to his preceptor, John Hunter. He settled the question, May 14, 1796, when he vaccinated a boy, James Phipps, with matter from a kinepock on the hand of a dairymaid, Sarah Nelmes, and on July 1st introduced into this boy pus from a smallpox pustule without effect. Two years later—June, 1798—he published "An Inquiry into the Causes and Effects of the Variolæ Vaccinæ," illustrated by four plates, and within a year or two vaccination became general over the continent of Europe.

Vaccination was introduced into the United States July 8, 1800, by Benjamin Waterhouse, Professor of Physick at Harvard University, who vaccinated his own children, and into Philadelphia by John Redman Coxe, who vaccinated his oldest child about the same time, and then tested the experiment by exposing him to the influence of smallpox. The reliance on the protective power of vaccination in America was strengthened materially by this bold act. President Jefferson was instrumental in introducing vaccination in Southern United States.

Once introduced, the practice spread rapidly, but not without some opposition, some of which prevails even at the present day, although it is as certain as any demonstrable fact that thousands of lives have been saved by vaccination, and that a thorough and continuous practice of the operation would, sooner or later, blot out smallpox from the face of the earth.

Publications in connection with the Jenner Centenary in 1893 have added greatly to the literature on vaccination, especially the centenary number of the "British Medical Journal." See the Report of the Royal Commission on Vaccination, the comprehensive article by T. D. Ackland and Copeman in "Allbutt's System," and the monograph by Cory. Also "Facts about Smallpox and Vaccination," leaflets issued by the British Medical Association ("British Medical Journal," 1893, vol. i. p. 632). See, also, Moore's "History of Smallpox," London, 1815.

It is impossible to follow the history of numerous epidemics of smallpox which have prevailed from time to time, even since the ravages of the disease have been arrested by the agency of vaccination. The latest epidemic characterized on the one hand by its widespread distribution, and its comparative mildness on the other, is that which commenced in the United States, at the close of the Spanish-American war in 1899, spread over almost every State of the Union, and is not, at this writing, completely arrested. Soon after the period above mentioned there appeared in the Southern States and elsewhere a disease which did not accord with the classic descriptions of smallpox, and was variously regarded as chicken-pox, smallpox, impetigo contagiosa, Cuban itch, and as an hitherto undescribed dermatosis.

In many cases the mildness of the illness was such that the patient could pursue his usual occupation. As a consequence of failure to recognize the true nature of the disease, it spread widely. Thus, there were reported in the United States to the Surgeon General, Public Health, and Marine Hospital Services in

YEAR	CASES	DEATHS
1898,	2,633	27
1899,	10,453	458
1900,	20,362	819
1901,	48,206	1127
1902,	54,014	2083
Total,	135,668	4514

The mildness of the epidemic is shown by the fact that the mortality for this period, and enormous number of cases, was only 3.3 per cent.

In the city of Philadelphia there were in the

Etiology.—The contagium of smallpox, probably the most unailing of all the contagia in its effect upon the unprotected victim, has not yet been isolated. It is conveyed in the secretions and exhalations of the body, including those of the lungs. The pus of the pustule is its most fertile

source, and the dust derived from the dried pus scales is the more usual medium of its distribution. No other pathogenic organisms than those of suppuration have been isolated from the disease. The degree of mildness or severity of a case does not influence that of another caused by it; the severest cases being at times followed by the mildest, and *vice versa*. The contagium is very tenacious, and may be dormant for months in clothing or furniture or hangings. No age nor sex nor race is exempt, but the number of cases in successive decades diminishes because of the immunity furnished by a previous attack. The *fetus in utero* may acquire the disease from the mother, and the child may be born with the eruption on it. Certain individuals are invulnerable even though unprotected by vaccination, while the mortality in aboriginal races is very great. Many alleged immunes respond to a proper vaccination.

Some difference of opinion exists as to the period at which smallpox is contagious. Welsh and Schamberg, in their forthcoming book on Contagious Diseases, make the following statement, which may be considered as embodying the most recent views:

"Smallpox is undoubtedly infectious in all stages characterized by symptoms. It is alleged by some that the disease is even infectious during the period of incubation, but we think there is very little reason to believe that such is the case.

"The disease is least infectious during the initial stage, and most highly so during the suppurative and early period of the desiccative stages."

Morbid Anatomy.—The essential morbid anatomy of smallpox is that of the eruption as represented by its various stages and modifications, including hemorrhagic infiltration. To the anatomy of the eruption is added that of the complications that may occur.

Fig. 15.—Temperature Chart of Smallpox—(Eichhorst).

The histology of the pustule shows that it starts in the *rete mucosum*, close to the true skin. The center is a focus of coagulation necrosis, and about it the reticular spaces are filled with serum, leukocytes, and fibrin filaments. As long as the process does not extend deeper, healing takes place without a scar. In the more severe cases the papillæ of the true skin are invaded to various depths and destroyed by the infiltration, producing a loss of tissue constituting the pit. Among other morbid phenomena may be mentioned a hardness and firmness of the spleen. Cloudy swelling of the secreting cells of the liver and kidney occur, as in other fevers with high temperature. True nephritis is rarely present.

Symptoms.—After a *period of incubation* of from seven to twelve days, and sometimes longer, the victim is seized with *violent muscular pain*, especially in the back. Often a *chill* or *chills* usher in the disease, and in children a *convulsion* may be the initial symptom. *Intense headache* is also present. *Fever* sets in rapidly and the temperature reaches 103° to 104° F. (39.4° to 40° C.) the first day. The *pulse* is rapid, hard, and strong at this stage. *Delirium* may be present and is sometimes very violent.

About the second day the *initial rashes* make their appearance. These have been especially studied by Theodore Simon,* Knecht,† Scheby-Busch,‡ and William Osler,§ although they are mentioned by some of the older authors, including Sydenham, Wood, Watson, Niemeyer, Trousseau, Marson, Munro, and others.

They include a *diffuse scarlatinous rash* and a *macular or measy form*, dark red in color and occupying a variable extent of surface. Either may be associated with petechial ecchymoses. Sometimes they are general, but as a rule they are limited to the abdomen, the inner surface of the thighs, or the lateral region of the thorax and axilla. Among Osler's cases was one of a true urticarial prodrome. While it is to be remembered that the coexistence of smallpox and measles and of smallpox and scarlet fever is possible, it is more than likely that the eruptions on which the diagnosis was based were really the initial rashes of uncomplicated smallpox.

On the *fourth day* of the disease, the *distinctive eruption* makes its appearance in the shape of *small red spots*, first on the forehead and wrists, whence it extends rapidly over the face and extremities, becoming quite general in the first twenty-four hours. At this stage the eruption is not unlike measles, but in another twenty-four hours it is decidedly different. The papules have acquired shot-like hardness. With the appearance of the eruption the fever falls and the patient feels comfortable. On the *fifth* or *sixth day* a clear or slightly turbid *serum* makes its appearance. Coincident with this a depression is seen in the middle of each vesicle. It is *umbilicated*, and this umbilication is the most characteristic feature of the eruption. Frequently, a hair follicle passes up through the center of it. By the *eighth day* the turbidity has increased until it is bright yellow and the umbilicus has disappeared. The *pustule is complete*. The maturation takes place in the same order as the eruption appeared. With the appearance of suppuration the fever again returns, known as the secondary fever, and with it elevation of temperature and other signs of fever. There is a good deal of pain in the inflamed parts because of the tension. On the *tenth* or *eleventh day* the *pustules* become *dry*, and by the *fourteenth* are converted into *crusts*, which drop off, leaving in mild cases a simple discoloration, in severe a more or less deep ulcer, or, if cicatrization be complete, a simple pit. The eruption may be found on the tongue and buccal mucous membrane and even in the pharynx, larynx, and esophagus, and pustules have been found in the stomach and rectum. In the trachea and bronchi there may be ulcers; also on the cornea. Sore throat, nausea, hoarseness, vomiting, and diarrhea may be consequences. With the drying of the eruption the fever disappears.

This description is typical of the course of the eruption in the simple

* "Das Prodromal-Exanthema der Pocken." "Arch. f. Dermatol. und Syph." Prag, Heft iii. 1870, 2-6; 1871, Heft ii. 242; Heft iii. 300; 1872, Heft iv. 541.

‡ "Arch. f. Dermatol. und Syph." Heft iv. 1872, 506.

§ "The Initial Rashes of Smallpox," "Canada Med. and Surg. Jour." 1875.

discrete variety. It may be variously modified. The attack may be so virulent that the patient dies before the eruption makes its appearance, or it may be arrested at any stage. Sometimes blood forms the contents of the pustule, and there may be subcutaneous infiltration of blood in addition. Along with this there may be hemorrhage from the mucous surfaces of the nose, stomach, or bowels, or there may be hematuria.

The pustules may be so close to each other that they join, when the case is *confluent*; or they may be separate and distinct, producing the *discrete* form. The variety with bloody infiltration is called *hemorrhagic*. The diagnosis as to whether the confluent or discrete form is present is generally made by an examination of the face, for it is an interesting fact that nowhere are the pock-marks more abundant than upon the face.

Sydenham early called attention to the fact that in the confluent variety the eruption appears earlier (on the third day), and its early appearance, according to him, is an indication that the case will be one of that variety. All the symptoms are much more severe. There is not the abatement of fever described as occurring on the appearance of the eruption. The face, hands, and feet present an almost continuous pus-vesicle, which often bursts in places, and the pus partly drying, there results a picture which is revolting. Such pronounced morbid changes must produce wide systemic exhaustion, as is manifested on the tenth or the eleventh day by the growing weakness of the patient, an adynamia that frequently terminates in death. When recovery takes place, the secondary fever is the more prolonged the more widespread the supuration.

The *hemorrhagic* variety of smallpox is still more severe. Two forms of it are described: One, the *purpura variolosa*, or hemorrhagic variola, in which the hemorrhagic symptoms appear early in the shape of a hemorrhagic rash while hemorrhage takes place from the mucous surfaces, generally on the evening of the second or third day. The patient dies in from two to six days, sometimes before the eruption makes its appearance. In the second form, *variola hæmorrhagica pustulosa*, the case progresses at first like any other, and it is not until the vesicular or pustular stage that blood makes its appearance in the pocks.

VARIOLOID.—A third variety of smallpox is *varioloid*, which is variola modified by vaccination or a previous attack of smallpox. In general, varioloid is smallpox bereft of all its serious features, each symptom being milder. The initial fever is less, the eruption is less general and may abort in its development, the secondary fever is less marked, and convalescence sets in earlier. Yet it has happened that both classes of individuals referred to, those having had smallpox and those having been vaccinated, have had very severe attacks, from which, indeed, the patients have perished. Generally, the longer the interval between the attack and vaccination, the more severe the former is. Similar is the mildness which characterizes a smallpox produced by the direct inoculation of an individual from the pus of another, though the attack thus caused is more severe than that which follows vaccination.

Other names given to less important varieties are *variola sine variolis*, or variolous fever without eruption; the crystalline pock, in which the eruption continues vesicular; and the "stone pock," "horn pock," and "wart pock," in which the vesicles dry up into tuberculated or warty elevations.

Complications.—Among complications of smallpox may be mentioned laryngitis with fatal edema of the glottis, bronchopneumonia, parotitis,

vomiting, diarrhea, albuminuria, but rarely nephritis. Prolonged delirium, and even insanity, have supervened, while neuritis may occur during convalescence; so may arthritis. On the skin may be boils and painful acne. A troublesome and painful conjunctivitis used to be the result of indifferent care of the eyes, but it is now less common because of greater care in this respect. Myocarditis and pericarditis sometimes occur, and most rarely endocarditis.

Diagnosis.—With the appearance of the perfect papule all doubt in the diagnosis of smallpox generally ceases. Ignorance of the initial rashes, measly and scarlatinal, has often led to errors of diagnosis. On the other hand, the resemblance of the eruption of *measles* to smallpox has also given rise to errors the result of which has been no less serious, because in consequence cases of measles have more than once been sent to smallpox hospitals with disastrous results. Never in measles is there such severe pain in the back as in smallpox, while the early cough and coryza are found only in measles. The lesson taught is to defer a positive diagnosis, because less serious mischief can result from an error thus occasioned than as the result of an opposite course. The possibility of *relapsing fever* being taken for smallpox has been alluded to in considering the former disease. *Cerebro-spinal fever* may also be simulated by the hemorrhagic form of smallpox. *Pustular syphilids* and accidental *croton-oil eruption* have been mistaken for smallpox, as has also chicken-pox.

Prognosis.—Smallpox is a serious disease, and the death-rate is always relatively large. It varies, however, at different ages, in different races, and in different epidemics. The young die almost always. Thus, in the Montreal epidemic of 1885, 86 per cent. of the deaths were children under ten years. The African and American Indian and native Mexican have perished by thousands. The range of the mortality in different epidemics is put down at 25 per cent. to 35 per cent. The recent epidemic in the United States was an especially mild one, the mortality being but 3.3 per cent. The hemorrhagic cases are always serious; those of *purpura variolosa* all die, and although some cases of *variola pustulosa hemorrhagica* get well, the majority are usually fatal on the seventh, eighth, or ninth day. The pregnant woman usually aborts and perishes, but not always. The complications of pneumonia and laryngitis are serious.

From the statistics of Dr. Gregory, based upon London hospital practice, most die on the eighth day; but in private practice, according to the experience of the late George B. Wood, the greatest number of deaths occur between the twelfth and eighteenth days.

Treatment.—It is not possible to cut short a case of smallpox. The patient should be isolated and taken to a smallpox hospital, if possible. If at home, an uppermost room should be selected, all hangings and carpet removed, and communication with the rest of the house cut off by closed doors fortified by a sheet dampened with a solution of carbolic acid, 1 to 60. Separate dishes and utensils should be provided, and nurses should hold no communication with other members of the family. All clothing removed from the patient should be put in scalding water, and sweepings should be burned. The nurse should wear an overall, to be removed on leaving the room, and her head should be covered with a close-fitting cap.

The treatment must consist in combating the symptoms. Morphine, or in less severe cases phenacetin, acetanilid, or antipyrin, must be given to control the pain in the back. Nourishing liquid food and stimulants are

required in adynamic cases. The fever is treated by sudorifics including acetanilid, antipyrin, phenacetin, and thermol, and by aconite, or by cool sponging or even by cold baths, as in typhoid fever, if the temperature be high. Cool drinks should be permitted *ad libitum*. The complications must receive the treatment appropriate to them. Tracheotomy may be demanded by edema of the larynx.

It has always been the object of the physician to find some means of preventing the disfiguring scars which so invariably remain after very severe cases. No one method is always successful. It has long been thought that the absence of light favored healing without pits. For the painful ophthalmia that so often attends smallpox, darkness is certainly a comfort, but that it diminishes the pitting I have much doubt. It is a comforting fact that even the deepest and ugliest pits gradually lose their distinctness as time passes, and that much of the marking disappears in the course of a few years. The surface should, however, be anointed with vaselin, cold cream, or similar substance, as they allay the burning and itching, keep the scabs moist, and prevent the contagium from spreading through the air. The odor, which is often intolerable, is perhaps best covered by adding carbolic acid to the vaselin or other unguent employed, say 10 grains (0.666 gm.) to the ounce (30 gm.); or a watery solution of carbolic acid may be made of the same strength and applied on cloths. Bichlorid of mercury, 1 to 2000, may be used in the same way. These preparations applied cold on lint are soothing and comforting. Dr. Schamberg, the assistant physician to the smallpox hospital in Philadelphia, says that, as the result of his experience in the epidemic of 1901-1902 in Philadelphia, painting with iodine seems to be more efficient in averting pitting than any other treatment. J. F. Romero claims to have used with most satisfactory results picric acid as a local measure to prevent pitting. He advises a lotion made with 2 grams (30 grains) picric acid, 15 grams (half an ounce) alcohol, and 185 grams (six and a half ounces) water. An ointment may be made instead. He suggests that the picric acid may destroy the pyogenic germs that may find their way into the pustules.

The eyes, nose, mouth, and throat should be kept clean, all crusts being carefully removed. This may be accomplished for the eyes by cold compresses frequently changed, while the nose, mouth, and throat should be cleansed with borated gargles and lotions. As soon as convalescence is established the patient should bathe daily, using carbolic soap, the bathing being kept up until the skin is perfectly smooth, because only then does the patient cease to be a source of infection.

Special Modes of Treatment.—As in the case of the other infectious diseases, smallpox offers encouragement to similar specific modes of treatment. The bacterium of smallpox, whatever it may be, does not seem to develop a toxic substance so virulent as that of diphtheria. The exhaustive effect on the system is that of the extensive inflammation and suppuration of the skin. The internal administration of antiseptics has been recommended, but seems to have furnished no results that particularly commend it. The substances tried are the usual ones—namely, sodium salicylate, salol, mercuric chlorid, carbolic acid, creasote, the sulphites, and sulpho-carbolates.

Upon the same plan as the serum treatment for diphtheria, serum from vaccinated subjects, both human beings and lower animals, and from smallpox patients in the advanced stage of the disease, has been used by Kinyoun, Lundmann, and Bécclère. Analogy would lead us to expect

similar results to those obtained by antitoxin in diphtheria, but such has not been the case as yet.

Special modes of external treatment, as by baths impregnated with antiseptics, have also been used and brilliant results claimed. Galewouski * used solutions of potassium permanganate of such strengths as to make the baths a rose-red color. He claims reduction of temperature, disappearance of pustules, and speedy recovery. Talamon † recommends external application of mercuric chlorid spray to the skin, using a solution made up of corrosive sublimate and tartaric acid, each 1 gm. (15 grains); 90 per cent. alcohol 5 c. c. (f̄ 1.25); ether, enough to make 50 c. c. (f̄ 1.33); spray three or four times daily for a minute, being careful to protect the eyes. The treatment is commenced on the first day of the eruption, being preceded by thorough washing of the face with soap, which is rinsed off with boric acid solution, and the skin then dried with absorbent cotton. After the spray has been used the face should be covered with a layer of 50 per cent. of glycerolate of mercuric chlorid to keep the skin antiseptic. After the fourth day the number of sprayings is gradually diminished, and after the seventh day they are discontinued, though the glycerolate dressings are kept up. Talamon also recommended in the confluent and grave forms of the disease mercuric chlorid baths lasting from three-quarters of an hour to an hour, with internal treatment including the usual supporting measures. These treatments commend themselves to reason and common sense, and as being disinfectant and cleansing at least.

VACCINE DISEASE.

SYNONYMS.—*Vaccinia*; *Vaccina*; *Сoxpox*; *Kinepox*.

Definition.—*Vaccinia* is an infectious disease produced by inoculation of man with lymph from the vesicle of *kinepox*. It is characterized by local and general symptoms. Persons successfully vaccinated are, in the vast majority of cases, immune from smallpox. The local product of such vaccination is the vaccine vesicle, the contents of which, when again inoculated, are capable of producing the same disease with immunity in another person not previously vaccinated. It is pre-eminently characteristic of vaccine disease that it can be communicated only when introduced directly into the blood.

Historical.—See History of Smallpox.

There can be no doubt that, if vaccination were thoroughly carried out, smallpox could be stamped out. This is, however, not done, and in point of fact, a few cases occur annually everywhere except in Germany, while at intervals an epidemic of greater or less severity occurs. A false sense of security leads to indifference about vaccination and revaccination, and thus gradually accumulate a number of susceptible persons who are liable to the disease.

Nature of *Vaccinia*.—Two views as to the true nature of *vaccinia* are held—the English, that it is smallpox modified by transmission through the cow; the second, or French view, that it is a separate disease distinct from

* "Med. Press and Circular," 1830.

† "Jour. of Cutaneous and Venereal Diseases," February, 1831, "Gazetta medica Lombarda," 1830.

smallpox. Each side claims that its own view is sustained by experiment. The former view is probably correct—that vaccinia is smallpox modified by passing through the cow.

Lymph in Use.—At the present time it is almost the universal practice to use animal lymph or the lymph directly from the cow, although humanized lymph, that from another person having vaccine disease, can also be successfully used. The chief reason for using animal lymph is that all danger of communicating other affections, especially syphilis, is thus avoided, although there is reason also to believe that protection is more certainly secured by animal lymph. For securing the cow-lymph numerous farms exist in this country and in Europe, where, under the most perfect sanitary precautions, inoculation is practiced on the udder of heifers, whence the lymph is gathered and distributed. In Belgium the heifers are slaughtered after the lymph is taken, and if they are found diseased, the lymph is not used. In this country the more usual method is to allow the lymph to dry on ivory points or quills, or to collect it in capillary tubes. Before the use of animal lymph became general the crusts, or scabs, from vaccinated arms were preserved and moistened to the consistence of pus before inoculation.

Bacteriology.—The inoculating element of vaccine virus has not been isolated. Analogy leads us to expect some organism will ultimately be found in the fluid of the pock. Quist has cultivated micrococci from vaccine lymph, which, he claims, produced in the child a typical vesicle; while Harold Ernst and Martin, of Boston, have isolated from bovine lymph a germ which grows on culture-media and produces, when inoculated in the heifer or children, characteristic vesicles. Klein and Copeman have each found a bacillus, and Pfeiffer and Ruffer bodies regarded as psorosperms. Peculiar ameboid bodies have been met in the blood of vaccinated persons.

Operation.—The operation of vaccination is variously performed. I prefer, after thorough cleansing, to scrape the skin of the arm or forearm with a lancet until the cuticle is removed and a moist surface results, due to the transuded liquor sanguinis. On this is expressed from the capillary tube the virus, or the ivory point is rubbed, slightly moistened. Prolonged friction is desirable to secure success. I am confident I have been more invariably successful since I have used capillary tubes instead of ivory points. It is a disadvantage to have the surface bleed much, as it interferes with absorption. Another method, handed down by the late Professor George B. Wood from his predecessors, and available only with liquid lymph, is to make three slight punctures obliquely under the cuticle and work the lymph into each. The punctures should be about a line apart and at the angles of an equilateral triangle. Very convenient instruments of various kinds are made to scratch the surface, which are especially useful when a large number of vaccinations is to be made and celerity is desirable. At the present day it is quite the fashion to inoculate on the leg, especially in the case of girls, in order to avoid an unsightly scar on the arm. In infants there is no objection to this, but I have known young girls to be very seriously disabled for a time by vaccination upon the leg. Another advantage of inoculation on the leg of infants is that there is less liability to injure the affected limb in nursing or carrying. The same thing is nearly as well accomplished by vaccinating the forearm, but this makes the resulting scar needlessly conspicuous. Another favorite situation is the region of the insertion of the deltoid muscle.

The Phenomena of Vaccination.—Immediately succeeding the operation a slight inflammatory redness appears, which usually subsides rapidly,

and sometimes has entirely passed away before the first phenomenon of the vaccine disease appears. Thus, there is a true period of incubation, after which, usually on the *third* day, but often two or three days later, a slight red elevation makes its appearance. By the *fifth or sixth* day this has already become an umbilicated vesicle filled with a transparent viscid fluid, surrounded by a delicate red areola. The vesicle presents a shining silvery appearance; by the *eighth* day it becomes a lustrous silver-gray, and by the tenth day the vesicle and areola have both reached their maximum. The pock is by this time 1-3 inch in diameter (about 1 cm.), one to two lines in height, umbilicated at its center, and presenting frequently a minute brown spot or scab in the same situation. The areola is quite angry looking, often two inches (5 cm.) or more in diameter, and shows under a magnifying glass numerous minute vesicles on its surface. At this stage, too, it itches and burns to a degree which causes in adults an almost irresistible desire to scratch, while in the child it gives rise to fretfulness and peevishness and to slight fever. Even in the adult there is slight rise of temperature. On the *eleventh or twelfth* day the disease begins to decline. The areola narrows and becomes less bright, the lymph more turbid and begins to dry. By the end of *two weeks* the vesicle has been converted into a dry, brown scab, which generally drops off on the twenty-first to twenty-fifth day. A scar remains, which is very distinct at first, but gradually assumes even a whiter hue than the surrounding integument.

The course described is the typical one in a healthy vaccinated child. In other cases the amount of local irritation is much greater, with a corresponding degree of constitutional disturbance. There is often adenitis in adjacent glands. Sometimes, in ill-conditioned children, deep, unhealthy ulcers supervene that are very slow to heal, while erysipelas and gangrenous ulcerations have even occurred and been followed by death. Even tetanus has succeeded upon vaccination and it has been claimed that the bacillus of tetanus has been inoculated with the germ of vaccine resulting in the simultaneous development of tetanus, but, so far as I know, none of the claims as to this combined inoculation have been substantiated. Tetanus resulting from simultaneous inoculation should appear 5 to 9 days after its introduction, whereas, in the cases commonly reported, 3 to 4 weeks have elapsed before tetanus developed. This seems to have been the case with the epidemic in Camden, N. J., in the fall of 1901.

Since the incubation period of vaccination is shorter than that of smallpox, the prompt vaccination of a person exposed to smallpox may protect him, or at least modify the disease.

Vaccination Rashes.—In certain cases, especially when vaccination is done with the liquid lymph from the cow, a general eruption of vesicles takes place, constituting *vaccinia bullosa*; associated with miliary vesicles it is called *vaccinia miliaria*. At times a roseolar eruption is associated,—*roseola vaccinalis*,—not unlike the roseolar eruptions of syphilis. The vesicles may be filled with blood—*vaccinia hæmorrhagica*.

Revaccination.—Should a considerable time elapse after vaccination, a revaccination will generally be more or less successful. Usually, the entire set of phenomena is less characteristic, although it sometimes happens that the same typical course is repeated. Such successful vaccination is regarded as evidence that immunity from smallpox is no longer present, and the person, if exposed to smallpox before vaccination, would have taken it. Such an attack is almost invariably less severe, and presents the modified symptom-

atology known as that of varioloid. The period of exemption after vaccination varies greatly. It is often perpetual. More frequently, it lasts from ten to twelve years, and every person should be revaccinated at ten to fifteen years, and thereafter whenever an epidemic of smallpox is raging, unless he happen to have been successfully vaccinated within a few years.

At times, even in first vaccinations, an abortive result obtains, the vesicle drying and dropping off much too early. Should this occur, the operation should be repeated.

Possibility of Transmitting Disease by Humanized Lymph.—It has already been said that the possibility of transmitting disease by vaccinating with humanized lymph has been a potent influence in stimulating the employment of animal lymph. Syphilis seems the only disease that can be thus transmitted, although it has been claimed also for tuberculosis. It is, nevertheless, important that every precaution should be taken against such accidents. If humanized lymph be used, as it sometimes must be, only that from children of healthy parents, free from syphilis or tuberculosis, should be selected, and under all circumstances *lymph admixed with blood should be rejected*. Lymph should be taken from fully matured and perfect vesicles on the eighth day.

It is exceedingly important that the physician should have at hand the data of discriminating between the ulcer of vaccinosyphilis and of vaccination; and between secondary vaccinosyphilis, the vaccination rashes, and hereditary syphilis occurring about the time of vaccination. Such data are found in the following table compiled by C. S. Shelly from Fournier, in Fowler's "Dictionary of Medicine":

VACCINOSYPHILIS OR VACCINO-CHANCRE.	VACCINATION ULCERS.
Chancre developed on the site of usually one or two only of the vaccination punctures.	Ulceration affects all the punctures, as a rule.
Inflammation is slight.	Inflammation and ulceration severe.
Loss of substance superficial only.	Ulcer deeply excavated.
Suppuration scanty or absent, scabs, or crusts.	Much suppuration.
Border of chancre smooth, slightly elevated, gradually merging into floor.	Margin of ulcer irregular, as in "soft chancre."
Surface of floor smooth.	Floor of ulcer uneven, suppurating.
Induration "parchment-like," and specific, not merely inflammatory.	Induration inflammatory only.
Inflammatory areola very slight.	Areola inflammatory and erysipelatous.
Gland swelling constant, indolent [syphilitic] bubo.	Gland swelling often absent; if present, merely inflammatory.
Complications rare.	Complications—sloughing, erysipelas, etc.—often present.
Chancre never developed before the fifteenth day after vaccination; usually not until after three to five weeks; it is still in its earlier stage twenty days after vaccination.	Ulceration is present twelve to fifteen days after vaccination and is fully developed the twelfth day after vaccination.
SECONDARY SYPHILITIC ERUPTION DUE TO VACCINOSYPHILIS.	VACCINATION RASHES.
Appears, at the earliest, nine or ten weeks after vaccination.	[Including roseola vaccinalis, miliaria vaccinalis, vaccinia bullosa, vaccinia hæmorrhagica; also accidental eruptions—rubeola, scarlatina, lichen, urticaria, etc.]
Requires, in every case, the pre-existence of a specific ulcer [chancre] at the site of vaccination.	A true vaccinal rash appears between the ninth and fifteenth day after vaccination.
	Absence of inoculation chancre.

Exhibits the character of a true specific eruption.
Fever often slight.
Lasts for a long time. Usually accompanied by specific appearances on mucous membranes.

Eruption does not exhibit specific characters.
Fever always present.
Evanescient.

VACCINOSYPHILIS

HEREDITARY SYPHILIS, SHOWING ITSELF ABOUT THE TIME OF VACCINATION.

Begins with local infection chancre and indolent bubo.
Typical development in four stages—viz., incubation, chancre, second incubation, generalization [secondary eruption], etc.
Never appears earlier than the ninth or tenth week after vaccination.

No chancre; begins with general phenomena.
Has no typical development in connection with vaccination.

Time of development quite independent of vaccination. Is attended by the characteristic syphilitic bodily aspects. Other manifestations of hereditary syphilis may be present. The history may indicate syphilis.

Some idea of the efficiency of vaccination may be obtained from the fact that through it smallpox has been blotted from the German army. Further, it was early shown by Marson that of those who have acquired smallpox after vaccination, the disease is vastly less severe than in those who have primary smallpox. This is confirmed also by the statistics of W. M. Welch, Physician-in-charge of the Municipal Hospital of Philadelphia. From a study of 5000 cases, he showed that where there were good cicatrices, only 8 per cent. died; with fair cicatrices, 14 per cent.; with poor cicatrices, 27 per cent.; unvaccinated cases, 58 per cent.

CHICKEN-POX.

SYNONYM.—*Varicella*.

Definition.—*Varicella* is an acute contagious disease of children, characterized by an eruption of vesicles with pearly contents and attended with little or no constitutional disturbances.

Etiology.—The disease is eminently contagious, but no specific causal organism has been isolated. It is almost purely a disease of childhood, occurring most frequently between the second and sixth year. It is a distinct and separate disease from smallpox, an attack bringing no exemption from that disease.

Symptoms.—The *period of incubation* is from ten to fifteen days. So slight is the constitutional disturbance that very commonly the appearance of the *eruption* is the first notification of the child's illness. At times there are *slight prodromal peevishness, restlessness, and feverishness*; at others there is a *slight chill* followed by *fever*. Some muscular pain may be present.

A prodromal scarlatinal rash may rarely present itself, but for the most part the *suddenness* of the *eruption* is *distinctive*. It presents itself in the shape of isolated pimples scattered over the body within the first twenty-four hours after constitutional disturbance. They may then appear first on the trunk, but are apt to be seen first on the face. In another twenty-four hours they are pearly pustules, as a rule, without umbilication or areola; and by the end of the third day they begin to dry up, and in another day are

converted into dark-brownish crusts, which drop off, usually leaving no scar. Sometimes, however, a distinct pit is left, especially if the pock be scratched by the child, as it sometimes is, because of the irritation it excites. Occasionally, too, the pustule is distinctly umbilicated and may also have a pink areola. The pustules appear in crops, so that on the fourth day they can be seen in all stages, but at the end of a week again all have disappeared. Rarely are there more than half a dozen on the face, though they may be quite numerous and the victim well dotted over. They occur also on the scalp.

I have never seen any complications with varicella, and in most cases under my observation the disease would have been overlooked but for the eruption. It is said, however, that *hemorrhagic pocks* sometimes occur accompanied by hemorrhage from the mucous membranes; that *nephritis* and even gangrene—*varicella gangranosa*—have occurred, and *infantile paralysis* has developed during an attack of the disease.

Diagnosis.—The diagnosis should not detain one long. The trifling constitutional disturbances, the rapid, almost sudden, development of the pustules, the absence of umbilication and of areola—all distinguish the disease from smallpox.

Prognosis.—This is invariably favorable, except in rare cases of *varicella gangranosa*.

Treatment.—Usually none is needed save the application of a simple lotion or ointment to allay the itching. The principal need of the physician is to make the diagnosis.

I conclude the section on the eruptive diseases with the following table, somewhat modified, from T. M. Rotch, which may be helpful in diagnosis:

	SCARLET FEVER.	MEASLES.	VARIOLA.	VARICELLA.	RUBELLA.
Incubation, . . .	Two to four days.	Seven to fourteen days.	Seven to twelve days.	Ten to fifteen days.	Fourteen to twenty-one days.
Prodrome, . . .	Two days.	Three days.	Three days.	A few hours.	A few hours.
Efflorescence, . . .	Erythema.	Papules.	Macules, papules, vesicles, pustules.	Vesicles.	Papules.
Desquamation, .	Lamellar.	Furfuraceous.	Large crusts.	Smaller crusts.	..
Complications and sequelæ, . . .	Kidney, ear, and heart.	Eye and lung.	Larynx, lungs, eyes.

WHOOPING-COUGH.

SYNONYMS.—*Pertussis*; *Hooping-cough*.

Definition.—Whooping-cough is an infectious disease, characterized by spells of coughing accompanied by a long-drawn inspiration producing the “whoop,” whence the disease is named.

Historical.—While the writings of Hippocrates, Galen, and Avicenna contain expressions that point to the existence of a specific disease like whooping-cough, it is still disputed as to whether this disease was known to the Greeks. The first published account appears to be by Baillou, in 1578. He described an epidemic occurring in Paris and spoke of it as a disease not previously known. A hundred years later, Willis wrote of *tussis puerorum convulsiva*, evidently the disease under consideration, which has since become omnipresent.

Etiology.—It is interesting to note that Linnaeus ascribed whooping-cough to the larvæ of insects in the nose. No specific organism has been generally agreed upon, though a number of candidates for this important rôle have been brought forward. Thus, in 1887, Afanassieff found in sputum from the disease a short bacillus, of which he has succeeded in making cultures, inoculations from which into the tracheæ of animals have produced catarrhal conditions. Letzerich also found a micrococcus in the sputum with which he claimed he was able to produce the disease in animals by introducing the sputum into the trachea. Koplik's bacillus seems better accredited, and is apparently the same as that described by Czaplewski and Hensel, as found in mucous clumps in the sputum.* Koplik found it in 13 of 16 cases. It is facultative anaërobic, and is not stained by Gram's method except in pure culture, in which it can be separated from other bacilli found with it. It is pathogenic for mice. It is found free and in pus-cells of mucus. It is not found in sputum during the prodromal stage.

Whooping-cough attacks children of all ages not rendered immune by previous attacks, though it is most usual between the first and second dentitions; nor is it a very rare affection in adults, in whom it may become serious. It is said to be more frequent in girls. Its epidemics are more common in the spring and winter, and often precede or follow those of scarlet fever and measles. The disease is generally communicated from one child to another, and few escape who are exposed. Sporadic cases also occasionally occur. The delicate and those suffering with bronchial and nasal catarrh are more vulnerable. Some persons are immune.

Morbid Anatomy.—There is no morbid anatomy peculiar to whooping-cough beyond the catarrhal inflammation. According to Myer-Huni and v. Heroff, this is most marked in the mucous membrane of the nose, larynx, and trachea down to the bifurcation, but especially on the posterior wall of the pharynx, and in the interarytenoid region—the so-called “cough region.” The morbid states found after death are those of the complications—viz., bronchitis, bronchopneumonia, and collapse of the lung. Vesicular and interstitial emphysema are sometimes present, the former from over-distention of the air-vessels, and the latter from their rupture.

Symptoms.—Whooping-cough has a *period of incubation* of from seven to ten days. There is no prodrome separable from the *preliminary stage*, beginning with cough which is in no way peculiar, being that of an ordinary cold with slight fever and without expectoration. There may be *coryza* and *injection of the conjunctiva*. This cough may go on for a *couple of weeks* and, if there be nothing in the history to suggest the nature of the disease, may occasion no suspicion. Toward the end of this period, however, the observing mother will have noted that the cough is gradually growing worse and becoming paroxysmal, that it occurs “in spells.” Then suddenly a “whoop” is noted and the nature of the disease is suspected.

The *paroxysmal stage* has replaced the catarrhal, and soon the diagnosis is plain. The paroxysms become more frequent and more severe. Each one begins in a succession of short expiratory coughs, which grow in intensity. All efforts lie in the direction of expiration, and all the expiratory muscles are brought into play to this end. *The chest is compressed laterally, and bulges in the sternal region.* As the result of such efforts, the face is flushed, the eyes are injected and bulging, the tears start, and the nose dis-

* For an exhaustive review of this subject with some original observations pointing to this conclusion, see a paper on “The Etiology of Pertussis,” by Joseph Walsh, in “Contributions from the William Pepper Laboratory of Clinical Medicine,” Philadelphia, 1900, p. 450.

charges. Finally, the paroxysm terminates or is interrupted by a loud, whooping inspiration—that is, it may end for the time or be immediately succeeded by another similarly concluded paroxysm. Severe paroxysms commonly terminate in an act of vomiting, which brings up considerable mucus, which often collects before the paroxysm begins and seems to be its exciting cause. The number of paroxysms in the twenty-four hours varies greatly. They may be as often as every half-hour or only four or five times in the day. Emotion will precipitate a paroxysm, as will the inhalation of irritant matters. The little patient resists the paroxysms as long as possible, and when the inevitable comes it will run to the basin or bowl, knowing full well what is to happen. The demure method pursued by little children under these circumstances is often at once touching and amusing. I have known each one of a family of a half-dozen children to have its own cup ready for seizure at a moment's notice. Rupture of a conjunctival or nasal blood-vessel sometimes occurs and occasionally an involuntary urination. An ulcer may form at the frenum of the tongue, said to be due to the pressure of that part of the organ against the incisor teeth. The termination of the paroxysm is followed by temporary relief.

The paroxysmal stage, if uncomplicated, is unattended by fever, and physical examination of the chest is barren of results as compared with the severity of the cough. The percussion note is clear, clearer during inspiration. Auscultation may discover a few moist râles soon after a paroxysm; but during it, nothing. Even during the whoop the vesicular murmur may be absent, because of the slowness with which the air enters the chest.

The *length* of the *paroxysmal stage* is usually from *four to six weeks*, although in mild cases it may be shorter. Indeed, there are mild cases of whooping-cough in which the paroxysms are scarcely noticeable and would not be noted except for an occasional "whoop." Toward the end of this period the paroxysms become less severe and less frequent, and soon the stage of decline or convalescence is established. In the course of it the paroxysms become still milder and less frequent, and finally subside altogether. They are, however, liable to be renewed for a time if the patient takes cold, and even digestive disturbances are said to have a similar effect. The other phenomena of the stage of convalescence are return of appetite, weight, and strength. The period of convalescence occupies another four weeks, so that the entire length of an ordinary attack of whooping-cough is from ten to twelve weeks, and even longer.

Complications and Sequelæ.—The complications that attend whooping-cough are bronchitis, bronchopneumonia, collapse of the lung, pleurisy, and interstitial emphysema. The bronchopneumonia is apt to be of the insufflation kind. Collapse of the lung may succeed it. Interstitial emphysema and even pneumothorax may result from rupture of the air-vesicles, and it is apt to become general and serious. In a case of this kind under the care of my friend, Horace Williams, which terminated fatally, an abscess formed at each point at which the emphysema approached the surface. Cerebral palsy and death from subdural hemorrhage are said to have occurred in whooping-cough. Among sequelæ may be mentioned, as a rare event, tubercular consumption; also permanent changes in the shape of the chest including the so-called pigeon breast, sometimes the result of a prolonged attack of whooping-cough.

Diagnosis.—The diagnosis cannot be delayed after the appearance of the whoop, and it is scarcely possible without it. Spasmodic cough may

occur from other causes, but it is not whooping-cough unless there be the whoop.

Prognosis.—Notwithstanding the enormous number of children who have whooping-cough and get well of it, many of them without any treatment whatever, it is not so harmless a disease as many suppose. At the same time I cannot believe that the position assigned to whooping-cough by Thomas M. Dolan,* of being third among the fatal diseases of children in England, is true of this country. The chief danger is from the complication of bronchopneumonia. The younger the child, the greater the danger. As already stated, cases in which interstitial emphysema occurs from rupture of the air-vesicles may terminate fatally. The disease is more serious in the negro race—more than twice as fatal as in whites.

Treatment.—The treatment of whooping-cough is one of the opprobria of medicine. Notwithstanding the claims of many to the contrary, it remains a fact that we possess no means of cutting it short. We may, however, palliate the disease by diminishing both the frequency and the severity of its paroxysms. The remedies to this end are the opiates, chloral, and antispasmodics. The former two, as a rule, should be reserved for night, though in severe cases chloral in doses sufficient to secure somnolence is recommended by Willoughby.† Of the latter, the most efficient are belladonna, the bromids, and asafetida. Belladonna should be given in full doses. It is difficult to name them, and they must for the most part be arrived at by trial. We may begin with 1 minim (0.066 gm.) of the tincture every two hours to a child of six months, or 1-12 grain (0.0055 gm.) of the extract, and increase the dose until the characteristic redness of the skin is produced.

The bromids, preferably of sodium, should be given as often, in doses of 1 or 2 grains (0.066 to 0.132 gm.) for every year of age. I am confident, too, asafetida is useful. I use it in the shape of a freshly spread plaster, large, so as to cover the whole of the front or back, and bandaged to keep in place. It should be renewed often. The odor is soon endured. Antipyrin has acquired some reputation and has been especially recommended by F. J. Taylor,‡ and Von Genser. The former says in many cases its action is little short of marvelous. He recommends beginning with a small dose, increased until a child of two years is taking two or three grains every three hours. The bromids of potassium, sodium, and ammonium may be combined with it. The same writer recommends alum to check excessive secretion in the later stages, three grains, every three or four hours, to a child two years old. Von Genser recommends two grains a day for each year of age and reports recovery in 24 days.

The intervals between the paroxysms at night may be prolonged by the judicious use of paregoric, deodorized tincture of opium or codein combined with the antispasmodics, including belladonna and the bromids.

The inhalation of germicidal solutions suggested by the probable germ origin of the disease has not as yet produced any results. Carbolic acid, 5 to 1000, corrosive sublimate, 1 to 4000, and the peroxid of hydrogen diluted with two parts of Dobell's solution may be used in this way. The remedies are better used with the steam atomizer, as the steam itself has a soothing effect.

Parents should be enjoined to protect their children from undue exposure, because it is this that causes complications, and it is the complications that are dangerous. Such complications, and other symptoms which arise in the course of the disease, should be treated by appropriate remedies.

The possibilities of serum therapeutics extend to the treatment of whooping-cough, and Dr. Walsh, in the paper alluded to, refers to results obtained by him which encourage further trial.

MUMPS.

SYNONYM.—*Epidemic Parotitis.*

Definition.—Mumps is an acute infectious disease characterized by inflammation of the parotid gland, sometimes of the submaxillary.

Etiology.—Although a *bacillus parotidis* has been described, it is generally conceded that the real contagium of mumps has not been isolated. Children and adolescents are its favorite subjects, the very young as well as adults being equally exempt. More boys are attacked than girls. The disease is more common in the spring and fall. It is more commonly epidemic, but may be sporadic. It may be associated with measles and whooping-cough. One attack protects against a second.

Morbid Anatomy.—The swollen and hardened salivary gland is the sole morbid product. The swelling is mainly due to serous infiltration.

Symptoms.—From seven to fourteen days intervene between exposure and the invasion, which is ushered in by *moderate fever*, rarely exceeding 101° F. (38.33° C.), although 103° and 104° F. (39.44° and 40° C.) have been noted. The first symptom is usually *pain below and in front of the ear*, but pain in swallowing may be first experienced. Simultaneously, there may be *swelling* about the ear, which extends rapidly in front of the ear and below it until the entire neck in this vicinity is involved.

The maximum swelling is reached in about forty-eight hours, after which the involvement of the other side begins and extends with equal rapidity. The most prominent point is in front of the ear. The swelling does not, however, subside as fast as it comes on, but persists from seven to ten days.

At the height of the disease the pain and difficulty in swallowing are extreme, the former extending often to the interior of the ear, producing earache, and the hearing may be affected. The parts are so tense and swollen as to make opening of the mouth almost impossible, mastication equally difficult. Suppuration is an exceedingly rare event. In cases of great severity delirium is sometimes present for a short time.

Complications.—The most frequent complication is *orchitis*, and occurring, as it commonly does, after inflammation of the salivary glands has subsided, it has been regarded as a metastasis; but this is probably not the case, since both conditions may be the result of the same cause, as originally held by Niemeyer. The swelling may affect one or both testicles, the duration being longer in the bilateral form. The organs are heavy and painful, but not so much so as in gonorrhœal orchitis. The inflammation lasts for three or four days and then subsides gradually. Usually, the gland itself is involved, but occasionally there occurs acute epididymitis with acute hydrocele and edema of the scrotum. Atrophy is said to have supervened.

Inflammation of the mammary glands and of the vulva sometimes occurs in girls, and more rarely of the ovaries.

Otitis media with resulting deafness, meningitis, and facial palsy are occasional complications.

Diagnosis.—The diagnosis usually presents no difficulties, and any doubt is commonly cleared up by the acuteness of the attack. Certain enlargements of the *cervical lymphatic glands* resemble contagious parotitis, and in scrofulous children the swelling in mumps is sometimes prolonged, but the physiognomy in this disease is different and distinctive. There is more swelling in front of the ear in parotitis, and in the first stage a triangular shape is produced with the apex downward, while the lobe of the ear is raised in a characteristic manner.

Prognosis.—The prognosis is favorable, no fatal cases of uncomplicated mumps being recorded.

Treatment.—No means of shortening the duration of the disease exists. The patient should be kept uniformly warm, and to this end the bed is desirable. It is usual to anoint the gland with some simple ointment, as cold cream, and it may be that the feeling of drawing and tension is thus relieved. No commensurate advantage results from leeching. It is thought by some that the so-called metastasis is occasioned by exposure to cold, and if this be true, there is even better reason for keeping the patient warm. Warm applications are generally better borne than cold. Cotton or wool or flannel, warmed and greased, gives a sense of comfort. Fever should be treated by appropriate remedies and other symptoms met as they arise.

SECONDARY PAROTITIS.—This term is applied to parotitis occurring as a complication in acute infectious diseases, typhoid fever, typhus fever, and pneumonia being the most frequent. It may be a complication of pyemia, phthisis, and carcinoma. Except in pyemia, when it is metastatic, it is probably caused by the bacteria of decomposing matters in the mouth, which reach the gland through the duct of Steno.

It is a much more serious affection than mumps, and often terminates in suppuration. Facial paralysis may result from destruction of the facial nerve, or there may be deafness from invasion of the middle ear.

The *treatment* of secondary parotitis is that of phlegmonous inflammation elsewhere.

INFLUENZA.

SYNONYMS.—*Catarrhal Fever; Grip; Fr., La Grippe.*

Definition.—Influenza is an acute infectious disease characterized by fever, by catarrhal irritation of any or all of the mucous tracts, especially the respiratory, by muscular pain, and by great prostration. It is commonly epidemic.

Historical.—Although influenza appears to have prevailed as early as 1173 in Italy, Germany and England, it was not until 1510 that it was recognized in its true light as an epidemic or pandemic disease. Since that date it has recurred at intervals of from four years to one hundred years. Up to 1870 more than a hundred epidemics had been described. It first appeared in the United States in 1627, in Massachusetts and Connecticut, and extended thence over South America as far as Chili. Since 1889 there has been an epidemic extending almost around the world. It usually begins in the east and travels westward. The last epidemic started in Bokhara, in May, 1889, reached St. Petersburg in October, Berlin in November, London in December, and the eastern cities of the United States by the middle of December. While its rate of travel is rapid, it is not more so than travel itself. Its spread is not influenced by the direction of prevailing winds. It travels as rapidly against the wind as with it, some observers say more rapidly. A district invaded in the fall of the year is apt to be infected more or less for several months. Since the epidemic of 1889 there has been some influenza each winter in the epidemic form in many American cities.

Etiology.—In 1892 Pfeiffer discovered in the pus-cells of tracheal mucus an organism which he regarded as that of influenza. It is 0.8 to 1

GRAPHIC CLINICAL CHART.

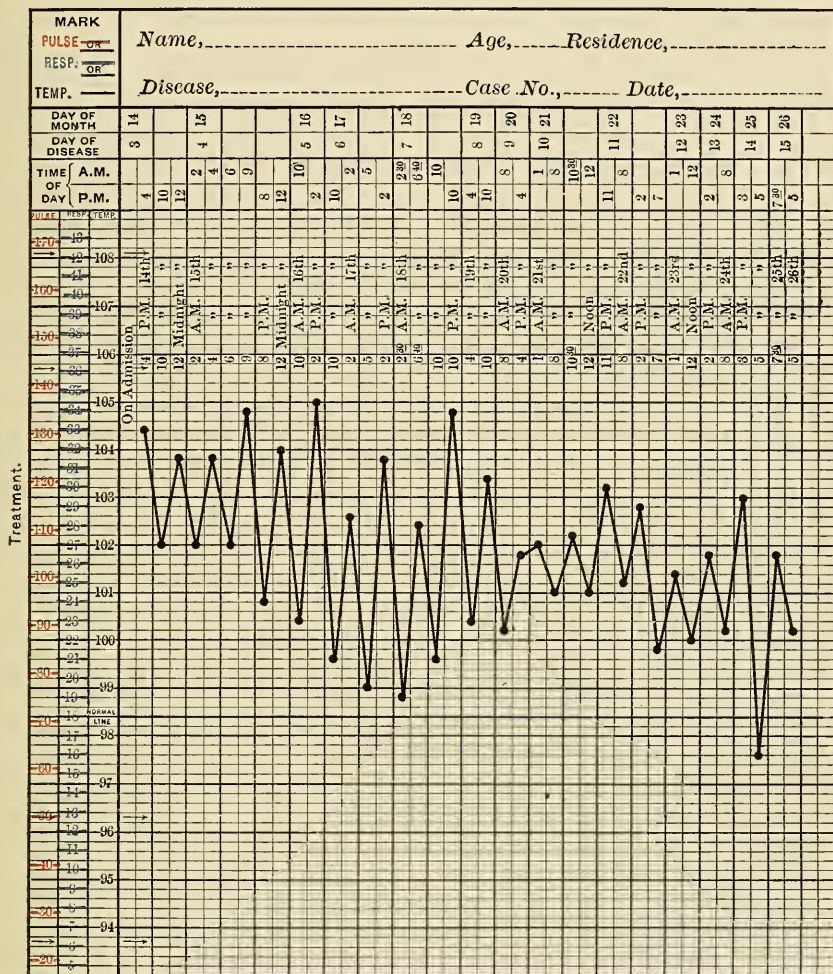

Fig. 16.—Chart of a Case of Influenza—Medical Student.

micon long and 0.1 to 0.2 micron broad—*i. e.*, about the same width as the bacillus of mouse septicemia and half as long. It forms colonies on glycerin agar twenty-four hours after inoculation, visible under the microscope as clear, water-like drops. These drops do not coalesce, but remain separate. The bacilli are best stained in dilute Ziehl-Neelsen solution of carbol fuchsin or hot Loeffler methylene blue solution. Later studies tend to sustain Loeffler's claim. The bacilli are very numerous in the nasal and bronchial mucus, whence they are conveyed to others, constituting a true contagium. P. Canon has even found them in the blood. The contagious nature of influenza is further sustained by the fact that it travels only as fast as people travel, even contrary to the direction of prevailing winds. The fact that inoculations have thus far been unsuccessful in transmitting the disease

is, however, against its contagious nature. The complications and sequelæ of the disease—pneumonia, pleurisy, endocarditis—may be the result of a toxin, or the bacillus may be transmitted in the blood to the seat of secondary infection. One attack does not, however, protect against a second, and I know persons who have had an attack each winter for several winters.

VARIETIES.—There is much carelessness at the present day in the application of the word "grippe." Commonly, when a person is said to have "grippe" it means that he has a bad cold in the head, with more or less bronchial catarrh. This seemingly is what Leichtenstern calls endemic *influenza nostras*, pseudo-influenza, or catarrhal fever, a special disease of unknown etiology, which bears the same relation to the true influenza as cholera nostras to Asiatic cholera. In addition, Leichtenstern makes two other divisions—(1) *epidemic influenza vera*, caused by Pfeiffer's bacillus; (2) *endemic influenza vera*, which often develops for several years in succession after a pandemic, also due to Pfeiffer's bacillus.

Morbid Anatomy.—The anatomical changes are those of the complications. Whatever alterations are the direct result of the disease itself for the most part promptly disappear after death.

Symptoms.—Influenza has a *period of incubation* of from two to three days or longer. It attacks all ages, infancy less commonly, more frequently persons from twenty to fifty years old. The mode of onset is by no means the same. The attack may be ushered in by a *chill* or continued chilliness. Most frequently, perhaps, there are *coryza* and *sneezing*, with or without watering of the eyes. To this succeeds *cough*, to which is commonly added, very soon, copious expectoration. The cough may be paroxysmal and be attended with prostration at the end of the spell. It is often persistent, while the bronchitis may pass into *bronchopneumonia* or a *croupous pneumonia* may supervene. Less frequently, there may be *faucitis*, simple, however, and not accompanied by ulceration or white patches. These symptoms are more or less associated with *muscular pain*, although not invariably. At other times the attack begins with severe *pain in the back* or *back of the head*, the *chest walls*, the *extremities*, or *throughout the muscular system*. Such pain is sometimes severe and sudden. Severe *headache* may be associated.

Another mode of onset is by an extreme and *sudden prostration*. I have known a man to step from a railroad station, apparently well, and in the course of a few hundred yards become so weak as to have to take a car to reach his home, though not distant. This prostration is apt to be prolonged even in mild cases far beyond what seems reasonable. *Mental depression* is a frequent symptom, and suicide and even manslaughter have been said to be its terminal acts.

There is always more or less *fever*. Commonly, it is slight at first, but sometimes very high, ushering in the febrile variety of the disease. I have known it to be 106.2° F. (41.2° C.) at the first observation of a patient. More frequently, it does not exceed 103° F. (39.4° C.), and it is often but slightly above normal. During convalescence the temperature may become subnormal, and in the patient alluded to there was a fall from 106° F. (41.1° C.) to 96° F. (35.6° C.) in a very short space of time. Further, the temperature chart may exhibit fantastic changes, as seen in that of the case of a medical student who made a good recovery after twenty-eight days' illness (see Fig. 16). *Delirium* is sometimes associated with the fever, and may come on suddenly and actively. The *pulse* is usually cor-

respondingly frequent, but some cases of uncommonly slow pulse have fallen under my observation.

While pulmonary catarrh is perhaps the most frequent catarrhal manifestation, it is by no means always present, even when there are pulmonary symptoms. I recall an obstinate case of bronchial spasm without any secretion whatever. In the epidemic, especially of 1893-94, in Philadelphia and vicinity, *gastric catarrh* was frequent, producing distressing nausea with vomiting, and adding greatly to the physical weakness. Severe *vomiting* may even usher in the attack, especially in children. More rarely there is *diarrhea*.

Hérpes is sometimes present. According as one or another set of symptoms predominates, the disease is said to belong to the respiratory, nervous, gastro-intestinal, or febrile form of influenza.

Complications.—The most serious complication is *pneumonia*. It is often invited by exposure during convalescence or in the attempt of a patient to fight out the disease without giving up. In these events it is usually ushered in by a chill and extends rapidly through the whole of one lung or even both lungs. When a part of the primary attack, the pneumonia is more apt to be catarrhal and circumscribed, creeping from the bronchi into the air-vesicles, and is less serious, although it may also be fatal, especially in old persons. At other times the inflammation is confined to the minute bronchioles, and we have the physical signs of a capillary bronchitis. It may be associated with pleurisy. Of *cardiac* and *vascular complications* endocarditis, pericarditis, irregularity of the heart unassociated with evident endocarditis or pericarditis, may arise. Sudden heart failure is to be remembered as a possible cause of death, as I have reason to know from experience.

Of *nervous* lesions meningitis and encephalitis have been noted, even abscess of the brain; also neuritis and optic neuritis; in fact, almost every form of nervous disease, though some of the conditions must be referred to errors of diagnosis, cerebrospinal fever being probably responsible for some. *Herpes*, when present, is probably a result of neuritis. Mention should not be omitted of *venous thrombosis*—phlegmasia alba dolens—as a complication of influenza, Leyden and Guttman having collected 28 cases.*

A most important fact to be remembered in this connection is the tendency of influenza to *develop latent disease into active disease*, and to make slight grades of organic affections more serious. This is particularly seen in connection with heart disease and kidney disease. A small albuminuria with no other symptoms may become, after an attack of influenza, an incurable and rapidly fatal Bright's disease.† A mild cardiac affection, scarcely noticeable by its symptoms, may become a grave illness with degeneration of muscular substance and dilatation of the cavities.

Diagnosis.—The diagnosis is ordinarily easy, although doubtless during an epidemic many cases are called influenza that are cases of simple bronchitis, faucial angina, or nasal catarrh. The diagnostic features in addition to the catarrhal factor are the *suddenness* of attack, fever of *short duration*, extreme disproportional *prostration*. Muscular rheumatic pains are characteristic, but not always present. *Cerebrospinal* fever and *influenza* are sometimes confounded. The distinction will be considered when treating of the former. I have more than once thought of a case in its incipiency that it was going to be one of *typhoid fever*, but the suddenness of onset, absence of the typical temperature of typhoid, of epistaxis, of diarrhea,

* "Deutsche med. Wochenschrift," No. 6, 1897.

† See a paper by G. Baumgarten on "Renal Affections Following Influenza," in "Transaction of the Association of American Physicians," vol. x., 1895.

together with the shorter duration of the illness, turned the scale in favor of influenza.

Prognosis.—The prognosis is generally favorable, especially if the patient goes to bed at once, or at least houses himself. Such a one is almost sure to be well in three, four, or five days. It is possible, however, for one attacked to fight through the disease without losing a day's time. But especially unfortunate is he if he fails in this attempt because of taking cold or inability to hold out longer against the debilitating effect of the disease. In the former he is apt to have pneumonia, in the latter he has to contend with extreme prostration. The prostration of the epidemic variety is something peculiar. The weakness is extreme, and the slightest effort, physical or mental, promptly convinces the patient of this. The duration of the weakness may be greatly prolonged, months being sometimes necessary to overcome it.

Treatment.—The treatment in the majority of cases is very simple. Rest in bed, without medicine, answers for a large number. Beyond this the treatment is mainly symptomatic, phenacetin, acetanilid, or antipyrin being generally sufficient to subdue the pains when present. Quinin is necessary in many cases to keep up the strength. In ordinary cases requiring such treatment I am in the habit of giving 5 grains (0.324 gm.) of phenacetin every four hours, alternating with 2 grains (0.120 gm.) of quinin as often, omitting the former when the pain has disappeared, but continuing the quinin. When the pains are very severe, the phenacetin may be given more frequently and even in larger doses. When headache is present caffeine should be added in doses of 1-2 to 3 grains (0.1 to 0.3 gm.). Larger doses of quinin may be needed. A favorite prescription at the Hospital of the University of Pennsylvania is a capsule of 2-1-2 grains (0.16 gm.) each of Dover's powder, salol, and phenacetin, every two or three hours. Another prescription is phenacetin and salol, of each 2-1-2 grains (0.16 gm.), and pilocarpin, 1-12 grain (0.005 gm.). Still another is phenacetin and salicin, of each 2-1-2 grains (0.16 gm.) and powdered camphor, 1-2 grain (0.035 gm.).

The cough may be treated with turpentine stupes and sinapisms to the chest; and when there are positive laryngeal symptoms, "Dobell's solution," sprayed into the larynx, is very useful. It may also be sprayed into the nasal passages, or cocain may be applied locally. Internally, the officinal solution of citrate of potassium in half fluid ounces (15 c. c.) doses every two or three hours, is helpful. When the cough is disturbing, small doses of morphin or heroin may be necessary; and if secretion has set in, ammonium chlorid in 5- to 10-grain (0.324 to 0.648 gm.) doses, with 15 minims (1 gm.) of syrup of squills and 2 drams (7.4 c. c.) of compound licorice mixture are sufficient to answer the purpose. If more stimulating effect is required on the secretion, the aromatic spirit of ammonium in half-dram doses (2 gm.), or carbonate of ammonium in doses of 5 to 10 grains (0.324 to 0.648 gm.) may be substituted. Opium may be given in large doses, or morphin in corresponding doses, to relieve pain, if required.

For the prostration, supporting measures are necessary, and stimulants may be called for. Whisky and milk are efficient. The entire absence of appetite and the complaint that all things taste alike are to be ignored, and the patient must be encouraged to take food, which should be made as attractive as possible. Strychnin is an admirable heart tonic, and may be given, 1-30 grain (0.00216 gm.), every six hours, increased, if necessary.

Treatment for the pneumonia, often so grave a complication, is at times extremely difficult. In a few cases "pneumonia fulminans" strikes the patient down so suddenly and violently as to make all treatment unavailing. Referring the reader for details to the section on pneumonia, it may be said that, as a rule, in the pneumonia of influenza, stimulating and restorative measures of a very positive character, rather than depressing agents, are indicated. The free use of alcohol and ammonia is especially necessary. Dry-cupping is never out of place, for it can do no harm, if no good. It may be repeated and should be followed during convalescence by a jacket of wool, to maintain warmth and a uniform temperature, but this is of doubtful propriety during the height of fever when we need measures to dissipate heat rather than to retain it.

One need not wait for the physical signs of pneumonia to present themselves before beginning the treatment. Given a chill after exposure, with no other cause to explain it, a pneumonia is almost inevitable. Often-times a pneumonic focus in the center of a lung does not furnish any physical signs, while to wait until it approaches the surface causes a fatal delay in the treatment.

Other complications of influenza are treated as when they are simple diseases. Overmedication should be avoided.

CEREBROSPINAL FEVER.

SYNONYMS.—*Epidemic Cerebrospinal Meningitis; Spotted Fever; Petechial Fever.*

Definition.—An infectious disease of sporadic and epidemic occurrence, microbic in origin and especially characterized by inflammation of the membranes of the brain and spinal cord.

Historical.—Cerebrospinal fever is a disease of modern recognition, for a long time confounded with typhus fever, and even with our present knowledge at times difficult to distinguish from it. Its distinct recognition dates back no farther than 1805, when Vieusseux, in Geneva, pointed it out as a separate disease, under the name *fièvre cérébrale ataxique*, although there can be little doubt that it existed previously. Sir John Pringall describes in his work on "Diseases of the Army," published in 1752, a hospital or jail fever that resembled cerebrospinal meningitis. In his history of "Epidemic Pestilences" Bascome speaks of a local epidemic in the autumn of 1802 at Roettinggen in Franconia. Symptoms that almost conclusively point to this disease are described in the histories of the great epidemics of Europe from the thirteenth century on. It appeared in 1806 in this country as an epidemic at Medfield, Mass.; in Canada in 1807; in Virginia, Kentucky, and Ohio in 1808; in New York and Pennsylvania the year after; at Grenoble and Paris, France, in 1814; again at Metz in 1815. It disappeared on both sides of the Atlantic in 1816. It reappeared at Vesoul, France, in 1822-23, prevailing more particularly in barracks, whence it extended to other places more or less until 1849. It prevailed in Italy from 1839 to 1845, and in Algiers from 1839 to 1847. In 1844 a short epidemic visited Gibraltar; a longer one, Denmark in 1845-48. It occurred in a mild form in Great Britain in 1846, and malignantly in Sweden in 1854; in Norway in 1859-60; in Holland briefly in 1860-61. Northern Germany was again invaded in 1863, Southern Germany in 1864, and Baden and Hesse in the same year; Austria and Russia mildly a year or two later, and in 1868 Turkey and its adjacent possessions mildly.

In the United States another visitation occurred in 1822-23 in Middletown, Conn., and in 1828 at Trumbull, Ohio; again in Middletown in 1842, since which time it has prevailed more or less in all the States, being especially severe in 1863-65 in Philadelphia and throughout the State of Pennsylvania. It has lingered in Philadelphia ever since, isolated cases being annually reported. The number of deaths in that city from 1863 to 1891 inclusive, as collected by Alfred Stillé and completed by William Pepper, was 2575. Since 1891 cases have occurred each year as follows: 1892, 22 cases; 1893, 35 cases; 1894, 18 cases; 1895, 17 cases; 1896, 7 cases; 1897, 10 cases; 1898, 24 cases; 1899, 146 cases; in 1900, 29 cases; in 1901, 9 cases; 1902, 4 cases. An epidemic prevailed in Maryland in 1892, in New York in 1893, and in Boston in 1897.

Etiology.—The direct cause of cerebrospinal fever is believed to be a micro-organism not altogether undisputed, possibly of more than one variety. It includes a special lancet-shaped diplococcus resembling the pneumococcus discovered by Weichselbaum in 1887, and called by him *meningococcus* or *diplococcus intracellularis meningitidis*. It lies within the polynuclear leukocyte. Weichselbaum's observations were confirmed by Heubner* in 1891, by Jaeger in 1895, and by Councilman,† Mallory, and Wright in 1898, and Osler‡ in 1899. In general these observers favor the view that this organism is the exciting cause of the disease. On the other hand, A. Netter takes strong exception, and says (volume xvi., "Twentieth Century Practice of Medicine," p. 191): "The pneumococcus can, without doubt, cause meningitis, and in spite of Heubner's experience, the rôle of the pneumococcus has been most surely established experimentally." He regards the meningococcus as a degenerate form of the pneumococcus. Osler§ also says: "That a primary cerebrospinal meningitis may be due to the pneumococcus is universally acknowledged." Mixed infections undoubtedly occur as attested by all observers. Other bacteria found with it are *staphylococcus pyogenes*, *aureus*, *citreus*, and *albus*, the *streptococcus pyogenes*, *pneumococcus*, the *bacillus coli communis*, and *bacillus lactis aerogenes*. While the disease may be regarded as contagious, it is not highly so, being somewhat like tuberculosis in this respect. That the infectious agent is always derived from an infected person is at least doubtful, the disease not being, as a rule, traceable to another having it, but appearing to arise rather in certain houses or localities where the necessary conditions prevail. Neisser has shown that the bacillus is transmissible by feeble atmospheric currents. ||

Predisposing causes are—cold, moisture, exposure, defective sanitation. Crowded buildings, barracks, and tenements have been favorite localities, especially in Europe. Depressing influences and the fatigue of long marches favor it. During the Civil War in America both armies suffered from the disease, but the mortality was not large. Sometimes the disease prevails in the country rather than in the city. It is more common in the young, attacking even infants of less than a year old. Sex and race seem to have no influence on the etiology.

Morbid Anatomy.—The external appearance of the body after death is not peculiar. Most characteristic are the remnants of the eruption, petechial or herpetic, but they are not constant. The *brain* and *spinal cord* are naturally the seats to which we look for morbid changes, and we find every degree of inflammatory condition, from slight hyperemia, such as may be found in any form of infectious disease, to intense congestion with injection of the pia-arachnoid, and finally a stage in which pus and fibrinous deposits, more particularly in connection with the pia mater, are abundantly present. Higher degrees of hyperemia involve even the calvarium as well as the dura. The arachnoid spaces may contain serum and pus, but

§ *Ibid.*

|| The following are the characteristic features of this bacillus: It occupies a position within the polynuclear leukocytes, whence the adjective term *intracellularis*. It takes the usual stains, and is decolorized by the Gram method. It forms on Loeffler's blood-serum "round, whitish, shining, viscid-looking colonies, with smooth, sharply defined outlines, which attain a diameter of 1 to 1.2 mm. in twenty-four hours" (Councilman). It is found in the cerebrospinal exudate, and has been isolated from blood, from pus from the joints, from pneumonic areas in the lungs, and from nasal mucus.

it is under the pia mater that we look for the inflammatory products—serous, fibrinous, or purulent, especially at the bottom of the sulci in the longitudinal and Sylvian fissures and at the base over the pons, the chiasm, and cerebellum. To a less degree the convexity of the brain is also involved, and even the brain substance may share in the hyperemia, while actual softening has been noted. Adhesions between the pia and the cortex are common, removal of the pia carrying the substance of the cortex with it. More rarely there is an effusion into the ventricles and the choroid plexus is congested. The walls of the ventricles may be softened, and in cases of long standing there is even hydrocephalus.

The *cranial* nerves, especially the auditory and optic, may be the seat of a neuritis, or bathed in pus infiltrating the lymph-sheaths. The muscular and trophic phenomena resulting from such involvement may be permanent.

The *spinal membranes* are similarly hyperemic, even to the extent of extravasation of blood at times. The same inflammatory products are found upon them as on the meninges of the brain. They are more frequently seen on the posterior aspect of the cord, but may be general. Ounces of pus have been removed from the spinal canal. Even the central spinal canal has been found dilated and filled with pus. There may be likewise inflammation of the substance of the cord. The roots of the spinal nerves may be compressed by exudate, producing localized paralysis, or may be themselves the seat of a neuritis, whence the characteristic clonic muscular contractions often present, while the irritation of the sensory roots gives rise to more or less intense pain. Certain malignant cases are of so short duration that there is no time for morbid changes to occur. In such the results of necropsy are negative.

Minutely examined, the exudate consists of polynuclear leukocytes inclosed in a fibrinous mass in which also diplococci are found. The brain and cord may also be infiltrated with pus-cells. In the more chronic cases there is thickening of the meninges, with scattered yellow patches representing exudate.

As to *other organs*, there is no characteristic involvement. The *spleen* may be normal in size or, if the illness has lasted some time, it may be slightly enlarged. There may be congestion of the *liver, kidney, stomach,* and *intestines*, and even extravasation of blood. The same is true of the *lungs*, in which there may be bronchitis or pneumonia, the latter not very rarely. *Endocarditis* and *pleurisy* are sometimes found.

Symptoms.—Cerebrospinal fever does not present an unvarying picture in its symptomatology, and to attempt to portray every unusual symptom would occupy undue space. Several varieties are described, viz., (1) the ordinary form, (2) the malignant form, (3) the mild form, (4) the abortive form, (5) the intermittent form, (6) the chronic form. Only the most characteristic symptoms will be given, first of the ordinary form and then of the most important modifications of it.

I. *The Ordinary Form.* No definite time of incubation is known. A *prodromal period* of short duration with headache and pain in the back or headache and vertigo may precede, but sudden onset is characteristic, often associated with a decided *chill*. *Projectile vomiting* is also a frequent early symptom. *Headache* and *pain in the back of the neck* and back promptly appear. Though usually severe, this pain is sometimes so slight as to cause the real condition to be overlooked. It is sometimes so sudden and severe

as to be compared to the sting of a bee. The muscles are rigid, and pain is increased on motion.

There is *fever*, but the temperature does not usually exceed 102° F. (38.9° C.). There is nothing characteristic in the fever, and the graphic chart shows no regular evening rise and morning fall. On the other hand, it is extremely irregular. *Hyperæsthesia* of the skin is a characteristic symptom. It is sometimes extreme, and as the disease increases in severity *rigidity* of the muscles of the neck and back becomes more marked. This muscular contraction may cause backward curvature of the head and even *opisthotonos*. *Clonic spasm* may also occur, though less frequent than tonic contraction. It is more common in children, in whom it may amount to convulsion and take the place of the chill. *Spasm of the muscles of the face* may occur, and of the eye-muscles, causing *strabismus*. Strabismus in any febrile case of doubtful nature should always lead to suspicion of meningitis. On the other hand, there may be *paralysis* of the face and eye-muscles, producing inequality of pupils, nystagmus, diplopia, and ptosis. More rarely there are paralysis and wasting of trunk muscles, including those of respiration. The auditory nerves may be involved, affecting the *hearing*, and intolerance of sound is a characteristic symptom, as is also photophobia due to hyperemia of the retina.

Delirium is very frequent, occurs early in the disease, and may pass into stupor or coma. The delirium may be maniacal, considerable effort being necessary to control the patient.

It has been stated of the *temperature* in this disease that it is rarely high. In some of the earliest descriptions of the disease—and there have been most interesting ones written almost a century ago—the writers speak of the skin as being cool. This was before the days of the clinical thermometer and the accurate measurement of temperature growing out of it. High temperatures do occur, though rarely, 105° F. and 106° F. (40.5° and 41.1° C.) being noted, and others even higher just before death. There is, however, no constant type. The temperature chart of the intermittent form resembles somewhat that of remittent fever, while sometimes the chart resembles that of the fastigium of typhoid fever in its spike-like delineation.

The *pulse* goes hand in hand with the temperature—that is, it is not very frequent at first, at least in adults. As the disease advances it grows more feeble and more frequent as the result of increasing debility of the patient. So, too, the *breathing rate* is not apt to be markedly influenced unless there be a lung complication.

The *urine*, as in other infectious fevers, may be scanty and albuminous; but it may also be increased because of the involvement of the nervous system. For a like reason there is sometimes glycosuria, and occasionally in severe cases Cheyne-Stokes breathing.

Another characteristic symptom is the *eruption*, although it is not present in more than one-half the cases. It is of at least two kinds—*herpetic* and *petechial*. *Herpes labialis*, although not always present, is nevertheless more frequent than in pneumonia. The herpes may be noted elsewhere than on the face—viz., on the trunk and extremities, extending exceptionally even to the ends of the fingers. The contents of the vesicles may be purulent: they may coalesce and break and dry, forming crusts. The petechial eruption is more general. It is an extravasation, and, like the similar eruption in typhus, does not disappear on pressure. The number of spots varies greatly; there may be only a few, or they may be very

numerous, fully justifying one of the names of the disease—spotted fever. It will not do, however, to exclude the disease by reason of the absence of these skin symptoms. The petechial eruption seems less common in the sporadic than in the epidemic form.

Other eruptions, as erythema, urticaria, sudamina, rose-colored spots like those of typhoid fever, pemphigus and ecthyma, have been noted. Gangrene of the skin has occurred as the result of pressure. Some trophic influence may, however, be responsible for it.

Arthritis is not infrequent, varying in different epidemics, reaching nearly 20 per cent. of the severe cases in the epidemic described by S. Flexner and L. S. Barker.* The arthritis is deforming and is analogous to the arthropathies more or less common in spinal cord diseases.

Sometimes the disease sets in with *diarrhea*, though more commonly there is *constipation*. The *tongue* is less apt to be dry than in typhus, probably because the patient is less disposed to breathe through his mouth. Jaundice has been met with, and may be due to infectious inflammation of the bile-ducts.

Leukocytosis is a constant symptom, increase being chiefly of the multinuclear variety of white cells. Vacuolation of blood cells has also been noted.

Kernig's Sign.—Kernig, of St. Petersburg, called attention to a symptom which is at times a valuable aid to diagnosis in meningitis where the spinal membranes are involved. It is tested for in the following way: The patient is propped up in bed in a sitting posture, with the thighs flexed upon the abdomen and the legs partially flexed upon the thighs,—a position commonly assumed by patients with prolonged spinal meningitis. An attempt is then made to extend the leg, when it will be found to be resisted by contraction of the flexor muscles, preventing its full straightening. In the recumbent position the leg can be straightened. When the patient cannot sit up in bed, the thigh may be flexed upon the abdomen and then an attempt made to extend the leg, which again fails if meningitis be present. Friis found the sign in 53 out of 63 cases, Netter in 45 out of 50, and J. B. Herrick in 17 out of 19. † It is said to be present in all cases of spinal meningitis, but is especially characteristic of the acute cerebrospinal form. It is apparently no measure of the degree of intensity of the disease. Netter explains it as follows: "In consequence of the inflammation of the meninges the roots of the nerves become irritable, and the flexion of the thighs upon the pelvis when the patient is in the sitting posture elongates and consequently stretches the lumbar and sacral roots, and thus increases their irritability. The attempt to extend the knee is insufficient to provoke a reflex contraction of the flexors while the patient lies on his back with the thighs extended upon the pelvis, but it does so when he assumes a sitting posture."

The Babinski or extension toe reflex (see p. 849) may be sought, though it is inconstant and occurs in hemiplegia and other results of lesions of the motor tract.

II. *Malignant Form*.—The malignant form of cerebrospinal fever is characterized by the suddenness of its onset and severity of its cardinal symptoms,—the chill, headache, coma, collapse,—followed by early fatal termination. There is little or no fever; indeed, the temperature may be subnormal. The pulse is feeble and slow, falling to 50 or 60 a minute, increas-

* "Am. Jour. of the Med. Sci.," 1894, vol. cvii.

† "Am. Jour. of the Med. Sci.," July, 1899.

ing, however, in frequency as the disease progresses. The breathing is labored. The urine is scanty and albuminous. But for the prevalence of the epidemic such fulminating cases could not be distinguished from like attacks of other infectious diseases. Such cases may, however, occur even sporadically. They may last but a few hours. They are more frequent in the beginning of an epidemic. The malignant form of smallpox is similar, and the presence of an epidemic of one or other disease must settle the question.

III. The *mild form* presents a corresponding mildness of symptoms, and only the presence of an epidemic leads to its recognition.

IV. The *abortive form* terminates abruptly after a sharp development of characteristic symptoms.

V. The *intermittent form* is characterized by remissions and exacerbations in the fever every day or second day, without, however, the regularity of intermittent fever, for which it is sometimes mistaken. The fever resembles rather that of pyemia.

VI. Finally, the term *chronic form* is applied to cases prolonged beyond the usual duration, in which the headache, gastric irritability, and vague neuritic pains reduce the patient to such an extremity of exhaustion and emaciation that he welcomes death as a relief to his suffering; or partial recovery may take place with crippled motion, defective senses, and severe pains, which are a source of constant discomfort. On the other hand, some remarkable recoveries, even in these advanced stages, are reported, so that one should not be discouraged from continuing therapeutic effort.

Complications and Sequelæ.—Of the complications of cerebrospinal fever, *croupous pneumonia* has already been mentioned as not infrequent as well as that it is sometimes difficult to say which disease is primary. The initial chill and herpes are characteristic of both affections, and close attention to other conditions must be given, such as the presence or absence of an epidemic, the order of appearance of the symptoms, the nervous and muscular preceding in cerebrospinal fever, and coming on later in pneumonia. *Other complications* are those which not infrequently accompany infectious diseases, including *pleurisy, endocarditis, pericarditis, polyarthritis* with possible suppuration, and others.

Of the sequelæ the most important are *blindness due to optic neuritis* and more rarely *keratitis, deafness* from disease of the labyrinth, *paralysis* more or less extensive, invading especially groups of muscles, including those of the face. There may be aphasia and defective articulation. There may be also persistent headache, shooting muscular pains, and mental weakness. Next to scarlet fever cerebrospinal meningitis is the most frequent cause of deafness. Even *chronic hydrocephalus* and *abscess of the brain* are included among sequelæ. Von Ziemssen says the former is indicated by "paroxysms of severe headache, pain in the neck and extremities, without vomiting, loss of consciousness, convulsions, and involuntary discharges of feces and urine." He also says that of the deaf and dumb in the institutions of Bamberg and Nuremberg, in 1874, a majority of the pupils had become deaf from cerebrospinal meningitis.

Nasal catarrh may be an early symptom, and Strümpell suggests it may precede and be the starting point of the invasion. The discharge often contains the meningococcus, as in ten out of fifteen cases in the Boston epidemic alluded to.

Diagnosis.—The diagnosis in epidemic cases is usually easy, although

it is more than probable that under such circumstances some cases are classified as cerebrospinal fever when they are really something else. During epidemics *typhus fever* is the disease with which it is most frequently confounded, especially as epidemics of typhus and cerebrospinal fever sometimes prevail jointly. The difficulty is greatest at the beginning of the attack, for as time passes the diseases diverge in symptoms. Typhus fever is not characterized by the severe pains in the head and back of the neck, nor by opisthotonos, both of which may, however, be absent in cerebrospinal fever, or be so slight as not to attract attention. In typhus fever the spots are more constant and numerous than in cerebrospinal fever. Herpes does not occur in typhus. The typhoid state may be equally pronounced in both, but in general it may be said to be more marked in typhus. The two diseases differ in their duration, typhus having a pretty definite duration of about two weeks, whereas cerebrospinal fever is either shorter or longer.

Among the diseases which embarrass is *muscular rheumatism*; more frequently than with typhus fever, perhaps, is it confounded at the onset with this disease. The muscular pains are similar, but the headache in cerebrospinal fever is a point of difference. Hence, too, as the disease advances, the diagnosis becomes plainer. The joint complications not infrequently associated also cause a resemblance to articular rheumatism, which may lead to confusion at first.

The isolated cases give most trouble. *Typhoid fever*, especially the meningeal form of typhoid, in which there is extreme headache and active delirium, simulates cerebrospinal fever in the beginning not a little, and I have known consultants to hold different views for some days. With the lapse of time, however, the diagnosis may generally be made. The onset of typhoid is also slow; as a rule, there is no vomiting nor severe muscular pain.

Pneumonia is another source of confusion, especially as the two diseases are sometimes associated, and it is almost impossible to say which is primary. Should it prove that the meningococcus is the sole cause of primary cerebrospinal fever, and the pneumococcus characterizes only the secondary form associated with pneumonia or one of the sporadic primary forms, the bacteriological examination will be of great assistance. The meningeal complications in pneumonia are more apt to invade the convexity, whence there arise muscular contraction and tremor, but not retraction of the head.

Tubercular meningitis presents some resemblance to cerebrospinal fever. While usually less sudden in its development, it is not always so. Delirium and stiffness of the neck, retraction, and even opisthotonos occur. It is, however, scarcely ever primary, and there are no skin symptoms. The termination of tubercular meningitis is invariably fatal. The presence of a focus of tuberculosis is a great aid to diagnosis.

Influenza, too, in one of its many forms occasionally simulates cerebrospinal fever, at times very closely. Extreme muscular pain is characteristic of both, and when influenza is associated with actual cerebrospinal meningitis, with delirium and stupor, as it sometimes is, one may be excused for being in doubt. Although both are diseases of short duration, influenza spends its fury earlier, and is thus a shorter disease unless prolonged by one of its complications. This feature, if other characteristic symptoms are wanting, may help us to a decision.

Quincke's lumbar puncture may be necessary to establish a diagnosis.

The operation is done with the patient lying on the right side, with knees drawn up, and the left shoulder turned forward. The needle of a large hypodermic syringe or antitoxin syringe is introduced midway between the third and fourth or the fourth and fifth lumbar vertebræ, below the spinous process, a little to one side of the median line, the thumb of the left hand of the operator being placed between the spinous processes as a guide. The needle should enter one centimeter from the median line on a level with the thumb,

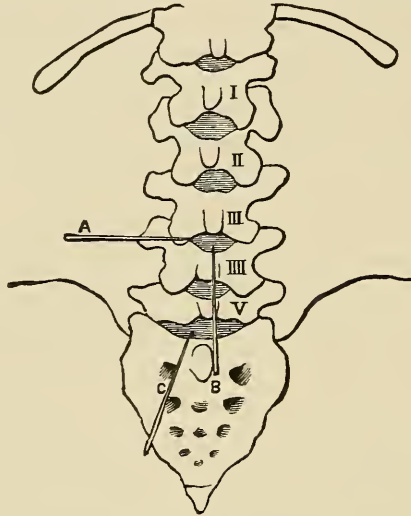

Fig. 17.—Method of Puncture for Spinal Drainage. A. Quincke's site. B. Marfan's site. C. Chipault's site.—(*Chipault.*)

and be directed slightly upward and inward. At the depth of two centimeters in infants and four to six in adults it should enter the canal. The syringe should be unscrewed and the fluid allowed to fall, drop by drop, into a sterilized test-tube, care being taken not to allow it to run down the side of the tube. Five to fifteen cubic centimeters should be withdrawn, for chemical, bacteriological, and microscopical examination. A faint trace of albumin is found in normal cerebrospinal fluid. It may be increased in cerebrospinal meningitis. A cloudy fluid is almost always present in epidemic meningitis; rarely, it may be clear, or the fluid from an upper puncture may be clear, and from a lower turbid. In tuberculous meningitis it is clear. Blood may be present in the former.

Prognosis.—Cerebrospinal fever is a grave disease, but the mortality varies greatly in different epidemics, ranging from 20 to 75 per cent. according to Hirsch, while v. Ziemssen places it for mild epidemics at 30 per cent., and for severe ones at 70 per cent. The death-rate is higher for children, those under two years almost invariably perishing, while few under five survive. The old likewise succumb easily.

Of few diseases is the course more variable and uncertain. From a duration of two to three days only it may be prolonged to weeks and even months, and its consequences may be permanent. Usually, however, improvement may be looked for if the patient survives five days, more than half the deaths occurring within this period. A remission of symptoms may take place on the third day, to be followed after a very short time by a relapse. This often misleads and gives the illusive hope of permanent

improvement. Convalescence is characteristically slow, the symptoms yielding gradually. If the termination be fatal, the cardinal symptoms likewise gradually subside, but are replaced by growing debility and exhaustion.

Relapses are prone to occur, prolonging the case indefinitely, while a chronic or protracted form, to which reference has been made, is probably due to the presence of one of the persistent or progressive lesions above referred to.

Sporadic Cerebrospinal Fever.—This form of cerebrospinal fever requires a separate, though brief, consideration. It has been already said that such cases occur at intervals, and more especially at odd times succeeding the prevalence of an epidemic in a city. Osler, in his Cavendish lecture, 1899, has taken some pains to analyze the cases of cerebrospinal meningitis treated at the Johns Hopkins Hospital, Baltimore, with a view to ascertaining what proportion was strictly sporadic and non-complicating. He finds that after eliminating pneumococcic meningitis complicating pneumonia and pneumococcic meningitis due to local infection and streptococcic cases of the same class (surgical cases), there remained a few primary cases due to the pneumococcus, a few of miscellaneous meningitis—*i. e.*, caused by unidentified bacilli—and a few due to the diplococcus intracellularis. The whole question is, however, unsettled because of the confusion that has existed until more lately of the pneumococcus with the diplococcus intracellularis.

Treatment.—The treatment of cerebrospinal fever is *symptomatic* and *supporting*. Quiet and the absence of disturbing causes, such as excess of light, too much company, are absolutely essential. The food should be simple and liquid, with an abundance of water. The symptom demanding the promptest relief is pain, and for this there is no substitute for *opiates*, and of these the best preparation is *morphin*, and the best mode of administration is by hypodermic injection. Doses sufficient to accomplish their purpose should be given, say 1-4 grain (0.016 gm.) to 1-2 grain (0.032 gm.), night and morning, for an adult. The tolerance for the drug is great. It may be combined with 1-150 grain (0.00054 gm.) to 1-100 grain (0.00064 gm.) of atropin. The same preparation may be given by the mouth if the hypodermic administration is not convenient, but the *deodorized tincture of opium* may be better borne, and where the more frequent administration of opiates is necessary, as hourly or bihourly, this preparation is to be preferred because of the possible harmful effects of the too frequent use of the hypodermic syringe. The action of the drug is, of course, to be carefully watched. Phenacetin, antipyrin, salicylic acid, and this class of drugs are no substitute for opium in this painful malady. Hot baths may be employed for the same purpose.

When there are spasms or convulsions there is no remedy equal to *chloral*. If it cannot be administered by the mouth, a dram (4 gm.) dissolved in 2 ounces (60 c. c.) of water may be given to an adult, without hesitation, per rectum. In extreme cases chloroform or ether may be inhaled for the same purpose. The bromids may be used as adjuvants in mild cases, but of themselves are altogether inefficient.

Cold may be applied to the head for the headache and other meningeal symptoms, and is best used in the shape of an *ice-cap* or ice-bladder or Leiter's coil. Cold may also be applied to the back of the neck and spine, and according to James Barr over the splanchnic region. These measures

must be discontinued when the temperature falls to normal. *Counterirritation* to the back of the neck and spine has long been employed, chiefly by blisters. At the present day it is regarded as of doubtful value. The *Paquelin cautery*, which has been of late much recommended as a substitute for the blister, can do no harm applied to the back of the neck. The inconvenience is less than is commonly supposed, and the ulcer heals rapidly. *Cupping* and *leeching* in the same localities, followed by warm fomentations, may be useful. They relieve the pain for a time at least. General bleeding is not recommended. Free movements of the bowels must be maintained by castor oil or calomel, and the bladder watched.

Quinin may be given in tonic doses of six to eight grains (3.8 to 5.9 gm.), but not for any specific end, while large doses are harmful, causing cerebral irritation. Measures of a very decided character to reduce the temperature are not, as a rule, needed. Simple sponging suffices for the most part. Should this be insufficient, however, tub bathing may be used as in typhoid fever.

The *nourishment* should be of the best, including animal broths and milk, and where, as is frequently the case in the early stages, they cannot be tolerated by the stomach, they may be given peptonized per rectum, not more than 4 ounces (120 c. c.) at one time. I have thus nourished for several days until the stomach became retentive a case despaired of, which ultimately recovered. Forced alimentation by the stomach-tube is recommended by Heubner. Alcohol is contra-indicated in the early stages unless there be unusual *adynamia*. Later, when exhaustion begins to show itself, it may be used and pushed as under similar conditions in other diseases.

There are no specifics that have sustained the efficiency claimed for them. The *bichlorid of mercury* and *iodid of potassium* have been most praised, and the former drug may be administered from the onset with some reasonable expectation that it may be useful in doses that need not be harmful if not beneficial. Such doses would be 1-24 grain (0.0027 gm.) every two or three hours for an adult, suitably reduced for children. Mercurial inunctions, which have been much used, are still recommended by v. Ziemsens, although he admits them to be of doubtful efficacy. Inunctions of *iodoform* ointment, 10 per cent., are advised by D. R. Brower.* The iodids and mercury are indicated in the later stages when there are symptoms of exudation.

The lumbar puncture is strongly recommended by Williams, Brower, W. Cuthbertson,† and others, as a curative measure; Wentworth is doubtful; Osler admits possible benefit therefrom. Laminectomy and local therapeutics, including drainage, have not furnished encouraging results at the Johns Hopkins Hospital.‡

The resulting paralysis should be treated by massage and electricity, and as already suggested we should not be discouraged from persisting, as remarkable cures have been accomplished.

Recently I have used with the most satisfactory results the subaqueous treatment recommended by Goldscheider§ to which my attention was called by Dr. William G. Spiller. It consists in active movements by the patient while submerged in a bath at a comfortable temperature. The movements are not passive, but active and voluntary.

ERYSIPELAS.

SYNONYMS.—*The Rose; St. Anthony's Fire.*

Definition.—An acute, contagious, primarily local disease, characterized by dermatitis with the usual signs of inflammation—swelling, heat, pain, redness, and a peculiar disposition to spread.

Historical.—Erysipelas was described by Hippocrates (B. C. 480), who had a remarkably clear conception of the disease. Its parasitic origin was first maintained by Henle (1840). Trousseau first asserted, in 1848, that an abrasion of the skin is an invariable condition of its origin. Hueter, in 1876, was especially conspicuous in claiming that the disease owes its existence to a micro-organism residing in the blood. Billroth and Klebs held similar views, but it was reserved for Koch, in 1880, to settle the question by finding the specific streptococcus in the lymph-vessels and lymph-spaces of the skin, though not in the blood. Fehleisen made the same discovery independently of Koch in 1881, isolating and cultivating the erysipelococcus and inoculating man with it. Orth had previously made experiments of the same kind on animals.

Etiology.—The *streptococcus erysipelatis* of Fehleisen is a minute, cleft fungus, a micrococcus in the narrow sense, three to four microns in diameter, arranged in pairs (diplococci) or chains (streptococci) of from six to twelve cells. The erysipelococcus resembles very closely the *streptococcus pyogenes* of Rosenbach—in fact, cannot be distinguished from it microscopically, while even the cultures of the two organisms resemble each other very closely. The *streptococcus pyogenes* grows more slowly and less uniformly, according to Hoffa, than that of erysipelas, and presents also a brownish discoloration in the middle of its colony. They behave very similarly when inoculated in animals. Simon asserts that the micrococcus of erysipelas is identical with that of pyemia. Klebs suggests that more than one organism may be concerned in the causation of erysipelas.

The organism probably operates as a local irritant producing the dermatitis. From this as a focus constitutional infection is set up, as in diphtheria, probably through the influence of a toxin generated by the micrococcus. The bacterium is found in the lymph-vessels and lymph-spaces of the periphery of the inflamed area, and not in the center, by which fact the peripheral spread of the disease is explained.

The organism is transferred from one person to another by direct contact, or by the intermediation of a third person, or through the atmosphere. It cannot be said, however, that the disease is highly contagious in the absence of surgical injury, for in my early experience as a hospital interne at the Pennsylvania Hospital, and later as a visiting physician in the Philadelphia Hospital, though it was the custom to keep the erysipelas cases in the ordinary medical wards, I cannot recall a single instance where the disease was communicated to another patient in the ward. It was very different, however, in the surgical wards, where the disease would spread rapidly from one patient to another, showing the importance of the open surface as a condition of the spread. The lying-in woman is very readily inoculated, so that no physician should attend a case of labor while attending one of erysipelas. Certain kinds of wounds, as lacerated wounds and scalp wounds, are especially prone to erysipelas. Clean-cut wounds in other locations suffer less frequently. Leech-bites, vaccination punctures, the wounds of the cupping scarificator and of the subcutaneous syringe, are also favorable starting points. Chronic inflammatory processes and skin diseases may also have erysipelas engrafted upon them.

Erysipelas is prone to occur in the epidemic form, more especially in

the spring * of the year in old and unclean hospitals, but such epidemics have become much rarer in the last twenty years. This is doubtless one of the results of antiseptics, now so generally practiced. The feeble, the intemperate, and those having Bright's disease or other affections weakening natural resistance, are more prone to the disease. An interesting case of Bright's disease under my care in the Philadelphia Hospital had frequent attacks of facial erysipelas, always accompanied by hematuria. *Relapses and recurrences* of erysipelas are prone to occur, and a person once attacked by erysipelas, far from being protected, is rather predisposed to a second attack. A family predisposition to erysipelas may exist.

Morbid Anatomy.—Like all acute inflammatory states of the skin, erysipelas fades away after death and leaves little, if anything, to be seen unless it has proceeded to the formation of blebs or abscesses. Swelling and corresponding deformity of the part, especially of the face, when extensive, may remain, but even this subsides with the lapse of time after death and may totally disappear.

Minute examination finds the cocci in the lymph-vessels and spaces at the periphery of the inflamed area, as already stated, and even in the uninfamed tissue beyond the margin.

Various complications attend erysipelas and add their morbid anatomy to that which is more essentially that of the disease. The most important of these are *pyemic abscesses* of internal viscera and *hemorrhagic infarcts* of the lung, spleen, and kidneys. The kidneys are especially apt to be congested, and the lesions of acute or subacute nephritis are sometimes found.

Symptoms.—The form of erysipelas which more particularly concerns the physician is the so-called *idiopathic erysipelas*, which arises independently of any apparent traumatic lesion, but since all erysipelas implies some lesion, however minute, the term is a misnomer. The fact remains, however, that the physician is most frequently called upon to treat the form of erysipelas in which there is no discoverable local lesion.

There is a *period of incubation* of from one to eight days, after which this variety of erysipelas begins at times with a *chill* or succession of chills associated with a *loss of appetite* and feeling of general discomfort. At other times the chill is wanting. In either event there soon appears a *small, red, burning spot* a few lines in diameter, usually on the face, oftenest on the bridge of the nose or on the chin. It spreads rapidly, and as soon as sufficient size is attained there is a very characteristic elevation of the patch above the surrounding tissue, which can be recognized by carrying the finger across it. This is of diagnostic value. The future extension of the process is upward over the forehead and laterally toward the ears until the whole face, and more rarely also the neck, is invaded. The eyes become closed by *swelling*, the features are distorted, and the sum of changes produces an appearance not soon to be forgotten. In other parts of the body, as the arms and legs, the same process may go on, but there is not the unsightly distortion found as in the case of the face and head. In some cases the process proceeds to suppuration, and deep-seated *abscesses* form. These

* The influence of the seasons is very well set forth by James M. Anders in a paper on "Seasonal Influences in Erysipelas, with Statistics," wherein he has shown, as the result of an analysis of 2010 cases collected from different sources, that the various seasons of the year exercise a potent influence upon the frequency of this affection. Thus, month by month the cases increase, in slightly varying ratio, from August to April, the latter month giving the greatest number, and then there is a rapid decrease from April to August, when we find the smallest number. Again, one-half of all the cases occur during the months of February, March, April, and May; and 15.9 per cent. during the month of April alone. It was found that a low barometer and mean relative humidity invariably correspond with the annual period in which the greatest number of cases occur, and that the highest percentage of relative humidity corresponds with the months affording the fewest cases.

must result from mixed infection with other pyogenic organisms, unless indeed the organism be the same as that of suppuration. *Blebs* form, particularly on the lobes of the ears and on the eyelids, while little vesicles are always visible through a lens. From these a serum may exude and dry on the skin. As the dermatitis extends to new areas, the earlier spots dry up and desquamate. The disease seldom lasts more than four days in one spot, although it may revisit the same spot during one attack.

There may be erysipelas of the mucous membranes, which may extend to the skin, or the reverse may take place—extension from the skin to the mucous membrane.

Fever probably always precedes, though not noted in the beginning, and it rapidly becomes higher, reaching as high as 105° F. (40.5° C.). There is a corresponding *frequency* of pulse, associated with *headache* and sometimes *delirium*. The fever continues as long as the disease continues to spread. Often a sudden drop, a crisis, occurs on the fifth to the seventh day, followed by another rise if the disease takes a fresh start.

In more serious cases fever and delirium may be followed by *drowsiness* and *stupor* and a *coated, dry tongue*—all the symptoms, in fact, of a typhoid state. The *urine* is scanty and a febrile *albuminuria* may be present,—in fact, to a degree, may be said to be constant,*—and nephritis sometimes results, while a pre-existing nephritis may have an acute exacerbation engrafted upon it. Mention has already been made, under the head of etiology, of *hematuria* occurring in these cases.

Gangrene may be associated with the deep-seated varieties, constituting gangrenous erysipelas.

Complications and Sequelæ.—The possible complications are numerous, but in practice are really not often encountered. The most frequent is *meningitis*, the result of extension by continuity through the openings of the cribriform plate of the ethmoid bone or by contiguity from the scalp through emissary veins of the skull, but I have never seen such a case. William Osler, however, traced the extension from the face along the fifth nerve to the meninges, causing an acute meningitis and thrombosis of the lateral sinus.

Edema of the glottis is the result of extension of the disease to the mucous membrane of the glottis. It is promptly fatal, unless relieved.

Malignant ulcerative endocarditis is also with comparative frequency secondary to erysipelas, three cases out of twenty-three being sequelæ of this disease. Of *cardiac complications*, pericarditis, endocarditis, and myocarditis; of *pulmonary*, bronchitis, pneumonia, and pleurisy may be mentioned as possible; also jaundice, dysentery, and hemorrhages from the nose and bowels. *Purpura* is an occasional complication. Nephritis of hemorrhagic variety has already been mentioned, and even glycosuria has been noted, possibly an accidental association. *Septic* and *pyemic complications* do, however, occur and are among the causes of death.

Among the sequelæ may be mentioned a *loss of hair*. *Cicatricial new formations* replace the parts destroyed by gangrene and may produce deformity by their contraction. On the other hand, hyperplastic new formations resembling elephantiasis Arabum may result. *Hyperesthesia* and *neuralgia* of the involved areas, *anesthesia* with which atrophy of the skin may be associated, symmetrical gangrene of the fingers, and painful affections of the joints have all occurred as sequelæ.

* See paper by J. M. Da Costa on "The Internal Complications of Acute Erysipelas," "Am. Jour. of the Med. Sci.," October, 1877.

Erysipelas may be associated with other infectious diseases, such as typhoid and typhus fevers, diphtheria, scarlet fever, and the like.

Diagnosis.—The diagnosis of erysipelas is usually not difficult, although many conditions are called erysipelas by the ignorant which are not of this nature. The acuteness of the disease, the rapidity of its spread, the constitutional disturbance and fever distinguish it from other conditions that superficially resemble it.

Prognosis.—The prognosis, in the vast majority of instances, is favorable. Only in the aged, the intemperate, and those of broken health from other causes does it prove fatal, as a rule. Complications, especially meningitis and septic states, are causes of death. On the other hand, erysipelas is said to exert a favorable influence on certain acute diseases, such as acute rheumatism, choroiditis, and even morbid growths. It has even been suggested to inoculate erysipelas for the cure of such affections.

Treatment.—The patient should, of course, be isolated. It is more than likely that a decided majority of cases of idiopathic erysipelas would get well without any treatment whatever. In other words, the disease is *self-limiting*. As the disease is exhausting, internal *treatment* should be *restorative* and *supporting*. Quinin, iron, nutritious food, and stimulants are indicated, while the patient should be kept at rest. The *tincture of the chlorid of iron* is used throughout North America because of some supposed specific influence over the disease, and doses as large as a dram every three or four hours have been given. I have always given iron, but never in such doses, and I am doubtful whether it exerts any specific effect of the kind claimed. The natural duration of the disease is short, and the effect claimed from the iron is no prompter than that which nature brings. Ten minims (0.666 gm.) every two or three hours are a sufficient dose, and it is exceedingly doubtful whether larger quantities than this are absorbed. Where debility is marked, alcohol in some of its forms should be freely administered.

J. M. Da Costa first suggested the use of *pilocarpin* in the treatment of erysipelas, more particularly in the early stages. J. L. Salinger,* A. A. Eshner, and S. D. Barr also report favorably on the same treatment, which should, however, be employed cautiously. It is recommended that 1-6 grain (0.01 gm.) be administered hypodermically every three hours until free sweating ensues. After this the interval is increased to four or six hours.

Of late, evidence is accumulating to show that diphtheria antitoxin possesses curative properties for diseases other than diphtheria. Among these is erysipelas. In all, five cases of successful treatment have been reported by Russian physicians. Presumably it is used as in diphtheria, which see.

An infinite variety of *local measures* has been suggested to arrest the spread of the disease, all of which are useless to this end, although some of them are useful in allaying the burning. For this purpose I know nothing better than the old-fashioned mixture of lead-water and laudanum in the proportion of four parts of the liquor plumbi subacetatis dilutus, U. S. P., to two of laudanum. Or a mixture may be made of acetate of lead 1 ℥ (1.3 gm.), powdered opium 90 grains (6 gm.), and water 6 f 5 (180 c. c.). Lead-water alone is an efficient local application for this purpose; so is cold water. In the military hospitals in Philadelphia during the late Civil War a cranberry poultice was a favorite application, and it was certainly a pleasant, cooling measure, but a waste of a useful fruit. Dusting the

* "Therapeutic Gazette," March 15, 1894.

surface with finely levigated oxid of zinc or subnitrate of bismuth also has a soothing effect. Of late, *ichthyol* has become a popular local dressing. It should be added to glycerin or collodion in the proportion of 2 drams (8 c. c.) to the ounce (30 c. c.) of glycerin or collodion.

A rational measure would be, as has been suggested by Heuter, the hypodermic injection of a 2 per cent. solution of carbolic acid, or a weak solution, say 1 to 4000, of corrosive sublimate, just beyond the edge of the advancing dermatitis, but it has never seemed to me necessary, while it is painful and annoying to the patient. There can, however, be no objection to using these antiseptics as dressings to the part.

SEPTICEMIA AND PYEMIA.

SYNONYM.—*Bacteriemia*.

Definition.—Pyemia and septicemia are general febrile conditions caused by the entrance into the blood of pathogenic micro-organisms. They are distinguished from sapremia, which is the condition of local development of micro-organisms associated with the entrance of their *toxic products* into the circulation but not of the organisms themselves. Septicemia and pyemia are sometimes included under the single designation of bacteriemia. They are in man caused usually by the entrance of pyogenic organisms—*streptococcus pyogenes* and *staphylococcus pyogenes aureus* or *albus*—into the blood. In septicemia the development of the organisms is not associated with a special localization of the micro-organisms in the internal organs with the production of abscesses, whereas in pyemia the presence of secondary pus foci in different organs of the body constitutes the distinguishing characteristic of the condition.

Etiology.—While the *pus* organisms have been heretofore held responsible for the majority of intoxications of the blood by their pathogenic products or toxins, from the medical standpoint the term *septicemia* may be applied to the toxic condition produced by any of the pathogenic bacteria which invade the blood and tissues with or without a visible site of infection. The proportion of these last has of late enormously decreased, because of the antiseptics practiced by surgeons, while the medical septicemias have not much diminished.

Illustrative cases of the more usual form of septicemia are puerperal fever following retained placenta, infection by scarlet fever or erysipelas or during difficult labor involving laceration, and the poisoning by a dissecting wound. Among medical septicemias may be mentioned those arising from typhoid fever, pneumonia, diphtheria, and gonorrhoea. These are all primarily local infections. The symptoms set in in from three to four hours to three or four days, more frequently within twenty-four hours.

The same essential cause lies at the bottom of pyemia as of septicemia, but associated with the former as important etiological factors are *thrombosis* and *embolism*. To this association Virchow first drew attention, and it is to thrombosis or embolism that the pyemic abscesses are due. Fragments of a venous thrombus due to phlebitis at the seat of putrid inflammation are broken off and carried in the circulation until a lodgment is effected. These fragments swarm with bacteria, causing intense inflammation which goes

on to abscess formation, producing the metastatic or embolic abscess. Emboli may be multiple and there will be as many abscesses as lodged emboli. A frequent source of multiple abscesses is the interesting disease, malignant or ulcerative endocarditis, itself a specific inflammation caused by some pathogenic organism floating in the blood and lodging on the heart valves, where it excites a septic valvulitis. The vegetations produced by this may be broken off and become emboli. These are carried through the arterial system to points of lodgment and constitute the arterial pyemia of Wilks. Osteomyelitis is also a cause of pyemia. The term *idiopathic pyemia* is applied to that form in which multiple abscesses coexist with the other symptoms of pyemia, but no infective focus is discoverable. It will be remembered that the non-infectious embolus produces simple hemorrhagic infarct.

The *seats of election* for abscess in pyemia in their order of frequency are as follows: The lungs, liver, spleen, kidneys, brain, and joints, the subcutaneous connective tissue, and subperitoneal connective tissue, including pelvic connective tissue. The marrow of long bones and the parts about the cavity of the middle ear are also seats.

Abscesses occur in the lungs when the septic emboli originate in osteomyelitis or in inflammatory affections of the periphery; in the liver, when they arise from septic foci in the portal area, especially in the intestines; the pelvic connective tissue, when they start in the uterus and its appendages; in the spleen, kidneys, and brain, if the emboli arise in the left heart, or are so small that they can pass from the right heart through the lungs to the left heart.

Suppuration is not limited to the agency of streptococci and staphylococci. The *gonococcus*, the *bacillus coli communis*, the typhoid bacillus, the *bacillus lancoletus*, and others are equally capable of producing suppuration.

Symptoms.—A rapidly rising *fever* is the first symptom of pyemia and septicemia, often so closely followed by a *chill* that its pre-existence is not suspected. The severity of the chill corresponds with the intensity of the infection and the degree of inflammation resulting from it. The temperature during the chill reaches 103° to 104° and 105° F. (39.4° to 40° and 40.5° C.) and is followed by a *sweat* and fall of temperature, after which the latter again rises to a point even higher than that first attained. Then follows another sweat and fall and thereafter a succession of intermissions, variable but quite characteristic. The rise is generally toward evening, and thus there is a certain resemblance to typhoid fever, while the rigors and sweats suggest malaria. The evening rise is by no means constant, and irregular fluctuations in the temperature are characteristic. There are other symptoms of fever—*viz.*, *thirst*, *loss of appetite*, and *nausea*. The *strength* of the patient rapidly wanes, he soon sinks into a condition of exhaustion and semiconsciousness, from which, however, he may be aroused to take medicine and nourishment.

The various local involvements cause *localized symptoms*. Emboli in the lungs cause cough and hurried breathing, but there may be no distinctive physical signs; in the liver, they may cause tenderness and enlargement with jaundice; if in the kidney, there may be no sign or there may be albuminuria and hematuria; if in the intestines, diarrhea; if in the skin, superficial abscesses; if in the joints, swelling, tenderness, and fluctuation; if in the brain, little is added to the existing nervous symptoms. There may also be secondary abscesses of the parotid gland and pancreas, the former

producing hard, painful swelling and the latter deep-seated pain in the epigastric and umbilical regions.

The *abscesses* contain the pyogenic bacteria, which are responsible for them.

Diagnosis.—The diagnosis is not usually difficult, though sometimes the disease is overlooked and the symptoms ascribed to some other cause. Reference has already been made to its resemblance to *typhoid fever* and *malarial fever*, but the physician should not be long in doubt. A careful study of the case will show marked differences in history, while the *status præsens* exhibits only a superficial resemblance. There are no rigors followed by sweats in typhoid fever, as a rule, and the temperature chart in pyemia is much more irregular. The suddenness of the pyemia is characteristic, though it is by no means invariable. In remittent fever the chill, fever, and sweat are more regular, the prostration is not so extreme, and, above all, it is promptly cured with quinin. The plasmodium, if found, definitely settles the question as to the malarial fever, and the Widal test that of typhoid fever. There should be no confounding of pyemia with simple intermittent fever. The complete absence of symptoms between paroxysms is in no way comparable to the evident desperate illness despite the temporary absence of fever in pyemia.

Among the causes of pyemia that have been overlooked is osteomyelitis. Gunshot injuries of bones and compound fractures, if followed by suspicious symptoms, should lead to investigation. Malignant or ulcerative endocarditis is often overlooked, and not without reason, as it is so often overshadowed by other symptoms. A cardiac murmur, with irregular temperature and sweating and unusual prostration, should excite suspicion.

Gonorrhœa and prostatic abscess are occasionally causes, as are also tuberculosis of the kidney and calculous pyelitis, the last two, perhaps, more frequently than the first two.

Prognosis.—The prognosis is very grave. Even when recovery takes place in comparatively mild cases, it is with shattered health. More fortunate are the rarer instances of recovery after puerperal pyemia, which, when they do occur, are more apt to be complete. When calculous pyelitis and even tuberculous pyelitis are causes, operation often furnishes prompt relief more or less complete.

Not all fatal cases are promptly so. There is a form of chronic pyemia lasting for months, in which the symptoms are less distinctive and in the history of an infected wound may be the only cue to its real nature. One such case came under my observation, that of a young physician who received a dissecting wound from which the symptoms started and which terminated fatally with meningitis after many months' illness.

Treatment of Septicemia and Pyemia.—First *remove*, if possible, the *primary surgical focus* and *relieve secondary foci* as they appear. After that the symptoms are to be combated and the *strength supported* to the utmost. To the latter end the most nutritious and easily assimilable food, quinin in liberal doses, alcohol freely, and strychnin are the sheet anchors. To these may be added sponging to lower the temperature. To check sweating, atropin, oil of erigeron in doses of 10 to 30 minims (0.65 to 2 gm.) in a capsule or on sugar; ergot 15 to 30 minims (1 to 2 gm.); agaricin 1 to 2 grains (0.06 to 0.13 gm.); the dilute mineral acids, 15 to 30 minims (1 to 2 c. c.). Antipyretics may be used to reduce temperature, but it is better to accomplish the same thing by hydrotherapy.

Among the more favorable cases, in which operative treatment is followed by prompt and sometimes more than temporary relief, are cases of septicemia originating in vesical and prostatic disease and calculous and tuberculous pyelitis. In tuberculosis of the kidney, as tuberculosis elsewhere, especially illustrated in the peritoneum, exposure to the air seems to have a destructive influence upon the bacillus. If the source of the infection cannot be reached by surgical measures, antistreptococcic serum should be used without hesitation. Twenty to 30 cubic centimeters should be injected every six to eight hours until decided improvement in symptoms takes place daily, after which the interval between injections should be increased. Smaller doses may be injected in milder degrees of the poisoning.

Prophylaxis is much more efficient than treatment, and with modern aseptic surgery and antiseptic obstetrics septicemia and pyemia are becoming much more infrequent.

HYDROPHOBIA.

SYNONYMS.—*Rabies*; *Lyssa*.

Definition.—Hydrophobia is an acute infectious disease of animals, communicable to man, and characterized by intense tonic spasm beginning in the larynx.

Historical.—The disease was known to the ancients, including the East Indians, Egyptians, and Israelites, but is not mentioned by Hippocrates (B. C. 460-357), though Democritus, living about the same time (B. C. 470-362), is said to have considered it a nervous affection allied to tetanus. Aristotle (B. C. 384-322), however, recognized it in dogs. According to Celsus, who wrote about the date of the Christian era, it was named *ὑδροφοβία* by the Greeks. The Latin poets, Virgil, Horace, and Ovid, mentioned it, as did also the historian, Plutarch (about A. D. 50-106), and Galen (A. D. 130-200), while Caelius Aurelianus (fourth century A. D.) discussed it. William Youatt first described it with accuracy in the lower animals and man.* Pasteur first showed its infectious character, and ascribed it to a toxin developed by a micro-organism as yet undiscovered. The disease is rare in this country and Germany, not infrequent in England and France, and common in Russia.

Etiology.—All animals are subject to the disease. The dog is the most frequent victim, and it is from him that it is almost invariably communicated to man. The wolf, cat, and skunk are also frequent subjects, and may communicate the disease to human beings by their bites, that of the wolf being especially virulent. In such cases, whatever the contagium may be, its bearer is conceded to be the saliva of the animal. The contagium is a fixed and not a volatile one. The researches of Pasteur go to show that it is also contained in the central nervous system, especially the medulla and brain. Klebs suggested that the disease is caused by a bacterium found in the salivary glands of those affected with hydrophobia. Gibier, Fol, and Babès claim to have found micrococci in the brain-substance, but these claims have not been confirmed by others, though their experiments have been repeated. There can scarcely be a doubt that an organism is the medium of infection.

The *period of incubation* is extremely variable, ranging from one week to two months or longer. Even two years are said to have elapsed before symptoms set in. The average may be put down at from six weeks to two months; but by no means all persons bitten take the disease, a most important point to be remembered in estimating the efficacy of supposed curative

* "Canine Madness," being a series of papers published in "The Veterinarian," 1828, 1829, 1830. London, 1830.

measures. Not more than 15 per cent. of those bitten by dogs, according to Horsley, become affected. Various causes contribute to this. Thus, the saliva may be wiped off in the transit of the tooth through the clothing, and such removal of virus may reduce the danger of the second bite of the same animal, even though it be on the unprotected skin. Again, the young are more susceptible. Bites on the face and hands are more frequently followed by infection than those on the lower extremities and remainder of the body. Statistics by Watson, in America, and by Bollinger, in Germany, show more cases to have resulted from bites in the upper extremities, while, according to Hofsley, wounds about the face and head are more apt to cause the disease than those on the hands, which are second in order, and after these come bites on other parts of the body. A much larger proportion of those bitten by wolves perish, from 40 to 80 per cent., according to different authorities.

To a very important practical question, How long after a bite may the dreaded suspense of an expected outbreak last? accurate answer seems scarcely possible. Yet, notwithstanding the fact that cases are recorded of an outbreak after an interval of two years, it may be said with confidence that if three months have elapsed, the victim may feel assured that he is safe.

Morbid Anatomy.—The morbid anatomy of rabies, so far as recognized, is limited to the upper spinal cord, medulla, pons, and cortex of the brain, and is revealed only by the microscope. The blood-vessels are dilated and congested, the perivascular sheaths are invaded with leukocytes, and there are even small hemorrhages. There is hyperemia of the pharynx, larynx, trachea, bronchi, and even of the mucous membrane of the stomach, which may be covered with blood-stained mucus. Often there are no discoverable changes.

During the year 1900, important discoveries in the minute morbid anatomy of rabies were announced by Van Gehuchten and Nélis. The changes were found in the peripheral ganglia of the cerebrospinal and sympathetic systems, and are especially marked in the plexiform ganglion of the pneumogastric nerve and Gasserian ganglion. In the normal state these ganglia are composed of a framework of tissue in the meshes of which lie the nerve cells, each one inclosed in a capsule made up of a single layer of endothelial cells. The rabic virus stimulates these cells to proliferation leading to the ultimate destruction of the normal ganglion cell and replacing it by a collection of round cells. The ganglion cells are sometimes only slightly altered, at others destroyed, the extent of the process varying in different animals, being most pronounced in the dog and less so in man and rabbit.

These changes are claimed to be especially valuable in diagnosis, since the examination can be completed within six hours after the death of the animal. It is important, however, that the animal should be allowed to die and not be killed prematurely. The ganglion selected for examination is by preference that of the pneumogastric nerve. The laboratory of the State Live Stock Sanitary Board of Pennsylvania was the first in this country to take up this method, under the direction of Dr. Mazyck P. Ravenel, bacteriologist to the Board. Fifty-two cases were examined between May, 1900, and July, 1901, without a single failure.

Symptoms.—Rabies is usually divided, corresponding to the prominence of symptoms, into two varieties—*furious* or *convulsive* and *dumb* or *paralytic* rabies. Professor W. H. Welch, of Johns Hopkins University, suggests a third form of *mixed* rabies, representing a combination of convulsive and dumb rabies. The variety common to human beings is

the furious or convulsive, though paralytic rabies also occurs in man, especially after bites on the lower extremities, and would seem to be increasing in proportion to the convulsive form. So, too, in dogs furious rabies is the more usual, while in rabbits the paralytic form is more common.

It is true, also, that a sharp distinction cannot always be made between the two forms, while a stage of excitation and a stage of paralysis may be made out in the same case, and it amounts largely to this: that in the furious form, the stage of paralysis may be short or wanting, while in the paralytic form the stage of excitement may be short and may be manifested only by acceleration of breathing, elevation of temperature, and symptoms referable to irritation of the vagus nerve. The most reliable observations go to show that there is no difference in the quality of the virus producing the two forms, but that the differences are due rather to peculiarities in the individual, the seat of inoculation, or perhaps the quantity of the virus.

The *first* or *premonitory* stage succeeds upon the period of incubation and lasts about twenty-four hours. The *cicatrix* of the bite, which has been for some time healed, may become painful or the seat of radiating pain, or become livid, or even break out again. The patient is *morbidly depressed* or irritable, is *feverish*, *loses appetite*, and is *sleepless*; there is *hoarseness* or huskiness of voice. A feeling of intense anxiety and a moodiness are very characteristic, his probable fate being the sole subject of contemplation. There is an increased excitability, as a result of which the banging of a door or a flash of light causes the patient to start.

The *second* or *spasmodic* stage is the true hydrophobic stage, setting in usually after the first twenty-four hours. It is also called the furious stage. The sum of its symptomatology depends upon an *exalted irritability* of the *muscles of the larynx*, as the result of which they contract upon the slightest irritation in their vicinity, the act of swallowing being the most frequent exciting cause. Attempt at swallowing is followed by the most *powerful contraction* associated with *dyspnea*, even when the glottis is open or tracheotomy has been performed; whence the *fear of water*, the contact of which with the throat is followed by such frightful spasm of the muscles of the larynx and elevators of the hyoid bone. Even the saliva, which is secreted in increased quantity, cannot be swallowed without exciting paroxysms. Hence it is discharged from the mouth, sometimes forcibly, giving rise to the popular idea that the patient is frothing at the mouth. A breath of air or the slamming of a door may produce a paroxysm.

The paroxysm may be associated with *maniacal excitement* in which the patient is sometimes uncontrollable, rolling his eyes, striking about with his arms, and making snapping noises with the mouth, which are compared to the biting of dogs. These noises are altogether due to uncontrollable spasmodic shutting of the mouth. On the other hand, between the paroxysms, when the mind is clear and the reason sound, there is often found a touching concern on the part of the patient lest he does some harm to those whom he loves. There is more decided *feverishness* in this stage, the temperature rising as high as 103° F. (39.4° C.), while the *pulse* is frequent and sometimes irregular. Albuminuria and glycosuria have both been found in this stage. The second stage lasts from *one to three* days, sometimes a little longer.

In the *third* or *paralytic* stage the patient has become exhausted. There are no more paroxysms and he is quiet. His heart gradually fails, and he dies by syncope, although he may die in a convulsion or in asphyxia. This

stage usually lasts from *six* to *eighteen hours*. Happily, the disease is one of short duration, ranging from two to six days, notwithstanding its long period of incubation.

Diagnosis.—Hydrophobia most resembles *tetanus*. Yet the diseases are very different. Hydrophobia has a long period of incubation, while tetanus has a short one, from three to ten days. Tetanus begins with trismus and is associated with opisthotonos. Neither of these symptoms is present in hydrophobia. Tetanus has no laryngeal symptoms, no spasms in swallowing. The mental depression so characteristic of hydrophobia is wanting in tetanus.

More difficult is it to distinguish hydrophobia from the imaginary condition known as *pseudophobia* or *lyssophobia*, numerous cases of which have been reported, and the occurrence of which doubtless furnished the foundation for the belief by some that there is no such disease as hydrophobia, and that all cases are lyssophobia. The resemblance is often very close, especially the depression and mania, and it is even said that strong men have been so overcome by this fear that they die as a consequence. The condition, however, generally passes away. Especially is this the case when it transpires that the biting dog was not rabid. Hence, the usual practice of immediately killing the dog supposed to be rabid is not a wise one, since it makes it impossible to settle the question conclusively as to its madness. It is better to confine the animal until the possibility of recovery is settled. If the dog be killed, inoculations from the medulla should be made under the dura mater of rabbits and results awaited. If true rabies, the paralytic form of the disease will be developed in from fifteen to twenty days. A much more rapid method of diagnosis is that recently announced by Van Gehucten and Nélis, for which see Morbid Anatomy.

Prognosis.—The prognosis once established of hydrophobia, is, unfortunately, totally unfavorable. The possibility of spontaneous recovery cannot be denied, but it is certainly exceptional. The preventive treatment is more successful. The claims of Pasteur will be considered under treatment. Youatt's success by cauterization with nitrate of silver is also there referred to. Bollinger's statistics go to show that out of 134 cases in which the bite was cauterized, 92, or 69 per cent., were attacked, while 42, or 31 per cent., died of the disease; of 66 not cauterized 83 per cent. died of the disease.

Treatment.—The curative treatment consists first in prompt measures to eliminate the poison. *Suction* is the promptest measure available and should be practiced, if possible, by the victim himself, as it is not without danger to a second person. An abrasion in the mouth or a carious tooth may be the medium of inoculating such person with the dreaded virus. If suction be practiced, the mouth should be promptly rinsed. It is doubtful if the cupping-glass is as efficient, even if at hand.

Next in availability is *cauterization*, which should be practiced by a *glowing hot poker* or other instrument of the kind, a galvanocautery or *Paquelin's cautery*. In the absence of such means *silver nitrate* or caustic soda should be used and thoroughly applied. Youatt considered nitrate of silver amply sufficient, having failed once only out of 400 times, and in this instance he declared that the patient died of fright. He himself was bitten seven times and in each instance used this agent. In the absence of these caustics *pure carbolic acid* may be used or corrosive sublimate, 1 to 500 or to 1000. When the symptoms once set in, palliation alone is possible. The sore should be kept open.

The *paroxysms* should be controlled by inhalations of chloroform, and averted as far as possible by full doses of opium, preferably, as a rule, morphin hypodermically. Chloral may at first suffice. As light and noise excite paroxysms, the patient should be kept quiet and secluded, and even in a dark room with two attendants. Water and nourishment may be given by enema.

Pasteur's Treatment by Attenuated Virus.—This is of the nature of preventive treatment. Pasteur discovered that the virus of hydrophobia is located in the nervous system, especially in the brain, medulla, and spinal cord. He then ascertained that inoculations by virus from this source in rabbits produced a virus of such increased virulence that after 25 successive inoculations there resulted a virus that acted after a period of incubation of eight days; and after 25 additional inoculations in seven days. The virus from the medulla of rabbits, with this short period of incubation, is called, "fixed" virus as contrasted with the "street" virus. Now, although the spinal cords of such animals contain the virus in a state of great intensity Pasteur ascertained that its intensity was greatly reduced by preserving the cords in dry air, and that it disappeared altogether in two weeks. The desiccation is practiced in sterilized glass vessels in which are placed pieces of caustic potash. If, now, dogs are inoculated with an *emulsion of such medullas* of reduced virulence, say, cords preserved from twelve to fifteen days, and then with the cord preserved for a shorter period—that is, with progressively stronger virus—they acquire immunity from inoculation by the fresh cord of the rabid rabbit.

Pasteur availed himself of these facts to *inoculate human subjects who had been bitten*. He used an emulsion of rabbits' cords that had been kept fourteen days, and on successive days made 12 more inoculations from cords preserved a shorter time, until those only one day old were used, after which immunity was secured. Later,—that is, in 1886,—Pasteur reported to the Academy of Sciences the so-called "intensive method," consisting in inoculations from cords of increasing virulence in more rapid succession, which is the method now commonly adopted in the various institutes. A careful examination of the results of this treatment by the most exact and conscientious observers, such as Victor Horsley, of London, and William H. Welch, of Johns Hopkins University, as well as the records of the numerous Pasteur institutes throughout the world, goes to show that the treatment is a powerful agent in saving life. In illustration it may be said that the treatment was commenced at the Pasteur Institute in Paris in 1886, at the end of which year the percentage of deaths was 0.94, while by the end of 1891 it had been reduced to 0.25 per cent., and for 1895 it was 0.13 per cent., or a mortality of 2 out of 1520 inoculations. In consequence of the difficulties in the way of carrying out the treatment it is practically available only at the Pasteur institutes referred to, of which there is one in New York City, one in Baltimore, and in almost all the large cities in Europe.

In the New York Pasteur Institute 1608 cases were treated in the 12 years expiring January 1, 1902, of which 10 died—a percentage of 0.62.

At the Pasteur Institute of Lyons 372 cases were treated from November 1, 1897, to November 1, 1899; 26 persons had been bitten on the face (6 per cent.); 203, on the hands; 143, on other parts of the body. In 58 cases (15.5 per cent.) the animal had been proved rabid; in 207 cases (55.6 per cent.) it was very probably rabid; in 107 cases hydrophobia was sus-

pected. Among the 372 persons treated there was but one death (0.27 per cent.).

At the Institute of Marseilles 1460 persons have been treated since its opening, five years ago. Six deaths occurred (0.40 per cent.). In 307 cases (21 per cent.) the animal inflicting the bite had been proved rabid; it was very probably so in 789 cases (54 per cent.).

At the Athens Institute 797 persons were treated from August, 1894, to the end of 1897. Two deaths were recorded (0.25 per cent.). Furthermore, the treatment failed in one case when a wolf had inflicted the bite. Among people not treated at the latter institute, 40 died of hydrophobia. In 27 cases the period of incubation was from twenty to one hundred and twenty days; in two cases it was from five to six months, seven months in one case, and twelve months in another.

The following directions have been issued by Paul Gibier, the Director of the New York Pasteur Institute, for the benefit of persons bitten:

Cauterization.—Theoretically, the *immediate* application to all the recesses of the wound of any agent that destroys protoplasm should suffice to kill any germs lodged therein and remove all danger of a general infection. Practically, such application cannot be made, and a later cauterization not only does no good, but does harm in lending a false sense of security to the minds of the patient and of his friends.

Treatment of the Wound.—It is best, then, to treat the wound as one would treat any infected wound.

When Should the Patient be Sent to the Pasteur Institute?—At once. It is not a hypothesis, but a demonstrated fact, that every day of delay adds to the uncertainty of a favorable prognosis. It is better to be inoculated for a disease that one has not contracted than to wait for a biological confirmation of infection, and then find that this delay is irremediable. The inoculation is, in itself, harmless to a non-infected person, and is also protective (like vaccination) for a period of several years.

What Should be Done with the Dog or Other Animal?—Whenever the animal can be confined and kept with perfect safety under observation, this should be done until he dies or recovers. As full notes as possible should be made and forwarded after the patient's departure to the Pasteur Institute, as a valuable part of his history. If keeping the animal is attended with unavoidable danger, it should be killed, the head separated from the body with an aseptic knife, and with a smaller aseptic knife a small piece of the medulla oblongata should be carefully extracted from the base of the skull. This should at once be placed in a clean, small, wide-mouthed bottle, containing a solution of equal parts of pure glycerin and water that has been sterilized by boiling. The bottle should then be sealed and forwarded to the Pasteur Institute for examination by animal inoculation, the results of which may not manifest themselves before three weeks. In addition, the stomach should be opened and examined as to the presence in it of food or of foreign bodies, and the details of this examination noted and forwarded as part of the patient's history.

How to Reach the Pasteur Institute.—The Institute is situated at 313 West Twenty-third Street, New York City. It is within easy access of the Sixth and Ninth Avenue elevated roads (nearest station at Twenty-third Street); the Eighth Avenue electric cars pass the other end of the block, and the Twenty-third Street cross-town cars pass the door from the Pennsylvania and the Erie Railroad Stations (Hudson or North River).

The Pasteur Department of the Baltimore City Hospital is at the corner of Saratoga and Calvert Streets.

Length of Treatment.—It is necessary in all cases for the patient to remain under treatment for fifteen days. During this time two inoculations are given daily. If the case is more grave—that is, if treatment has been begun late—or if the wounds are on the head or face, from four to six inoculations are given daily.

Beyond these measures the treatment of the disease is the treatment of the symptoms.

TETANUS.

SYNONYM.—*Lockjaw.*

Definition.—Tetanus is an infectious disease characterized by paroxysms of tonic spasm, repeating themselves with increasing severity. It is a disease of human beings and lower animals.

Etiology.—The specific cause of tetanus is a bacillus, which was isolated by Nicolaier in 1884 and obtained in pure culture by Kitasato in 1889. It is a slender rod with rounded ends, develops at ordinary temperatures, and is found in the soil, in pus, and putrefying fluids of wounds, sometimes forming threads, sometimes irregular masses. It is non-mobile, anaërobic, refusing utterly to grow in the presence of oxygen; develops spores within itself, though when studied early in pus is often sporeless. It is one of the most invulnerable of bacilli, its spores resisting a temperature of 176° F. (80° C.), while the bacilli retain their vitality in the dried condition for months. According to G. M. Sternberg, they resist a five per cent. carbolic solution for ten hours, but will not grow after fifteen hours' immersion. If five per cent. hydrochloric acid be added, they are destroyed in two hours. They are destroyed in three hours by a 1 to 1000 bichlorid solution, but when five per cent. hydrochloric acid is added the spores are destroyed in thirty minutes. Exposure to passing steam for from five to eight minutes kills the spores. The toxin, on the other hand, is rapidly destroyed by heat and light, being unable to resist a temperature above 140° to 149° F. (60° to 65° C.). In the dark in a refrigerator it can be kept indefinitely. Cultures of the tetanus bacillus in all media give off a peculiar characteristic odor—a burnt-onion smell with a suggestion of putrefaction.

The bacilli do not, however, pass into the blood, but at the site of the wound manufacture with great rapidity a ptomain or toxin, which is absorbed and excites the disease.* This was first shown in 1890 by Kitasato, who found that the bacteria-free filtrates of bouillon cultures of the tetanus bacillus produce the same symptoms as inoculation with cultures containing the bacillus, including ultimate death. Indeed, Brieger in 1886 isolated from impure cultures three ptomains, which he called *tetanin*, *tetanotoxin*, and *spasmatoxin*. The first of these causes the characteristic symptoms of tetanus; the second, tremors, convulsions, and subsequently paralysis; and the third, intense tonic and clonic spasms. More recently, Kitasato and Weyl obtained Brieger's tetanin and tetanotoxin from pure cultures; while Brieger himself, with Fränkel and Kitasato, has succeeded in isolating from tetanus cultures a far more deadly ptomain, *toxalbumin*, which was purified by Brieger and Cohn, who have shown that it is not a pure albuminous body.

* Hochsinger alone claims to have found the bacilli or their spores in the blood of tetanic cases.

Brieger has also isolated such poisons from the organs of those dead of tetanus, and Nissen has demonstrated toxin in the blood of those ill of tetanus.

Further, it has been shown by Behring and Kitasato that there exists in the blood of animals immune to tetanus a substance with opposite properties, therefore called antitoxin, and by the gradual introduction of the toxin into animals these observers have been able to produce in their blood a potent antitoxic substance. Such serum is prepared by Behring and by Roux abroad, and by the Mulford Company in Philadelphia. The method for its production is similar to that for diphtheritic antitoxin, but slower. Tizzoni and Cantani have successfully prepared it in a solid form, in which, it is claimed, it can be kept indefinitely and shipped as wanted, and applied it to treatment of cases of traumatic tetanus with success. Six cases have been thus treated up to December 24, 1892. "The Lancet," for August 10, 1895, contains a review of 35 cases treated at all stages with antitoxin, 23 successfully. More recently, Gooderich collected 153 cases with 63 per cent. of recoveries.

Predisposing Causes.—The excitation of tetanus is favored by certain conditions. *Wounds*, particularly contused and punctured wounds, especially of the hands and feet, are favorite foci, whence the term *traumatic* for such cases of tetanus, and *idiopathic* for cases not thus caused. A similar focus is the badly cared-for umbilical cord, whence *tetanus neonatorum*, affecting especially the colored race. In certain parts of the West Indies it is said that more than half the deaths among negro children are due to this cause. It is probably because the contused wound affords a more favorable nidus for the growth of the bacilli rather than that there is any peculiar laceration of nerves, as formerly thought. It is more common, too, in *hot countries*, and in places and seasons where there are decided alternations of heat and cold. It affects both sexes and all ages, but it is more frequent in men for obvious reasons, the average percentage of cases, according to F. X. Dercum,* being 22.

Idiopathic tetanus is much more rare than traumatic, and it constantly happens that close examination in cases of apparent idiopathic tetanus results in the discovery of a previous undiscovered trauma. *Exposure* to cold, especially damp cold, is one of the recognized causes of idiopathic tetanus. It can only produce a condition favorable to the lodgment and multiplication of the bacillus.

That tetanus should occasionally prevail in epidemics is one of the natural results of its mode of causation.

Morbid Anatomy.—There is no essential morbid anatomy of tetanus. There may be congestion, extravasations, and perivascular exudates due to impediment of the movement of the blood during spasm, granular changes in cells from modified nutrition—all results rather than causes of symptoms.

Symptoms.—A *period of incubation* of from ten to fifteen days is required for the operation of the specific cause of tetanus. Occasionally only does a *chill* precede the other symptoms. There appears first usually a *stiffness in the neck* and *jaws* and the patient opens his mouth with difficulty, but not with pain. Then the stiffness extends to the back and abdominal muscles and to the legs, which may be fixed in extension, more usually during a paroxysm. The result is that the abdominal muscles feel like a board and the whole trunk is inflexible. If an attempt be made to flex the

* Article "Tetanus," Keating's "Cyclopedia of Diseases of Children," vol. iv. p. 913, 1890.

thighs on the abdomen the whole body comes up in a single piece; if the body is turned over, it is like turning over a wooden man. There is, in a word, *orthotonos*. Again, as in a striking case of my own, the symptoms may begin in the abdomen and by its intermittent character simulate cramp.*

These symptoms are present in various degrees, less marked in the mild cases, more so in the severe ones. In severe cases the jaws become locked, in milder ones they may partly yield to forcible extension. The eyebrows may be raised and the angle of the mouth drawn out, producing the *risus sardonius*, or tetanic grin. In the so-called head tetanus described by E. Rose, there may be *paralysis* of the facial muscles and difficulty of swallowing, with violent *spasm* of the *pharynx* and *esophagus*. It is associated more particularly with injuries to the fifth nerve.

All the symptoms are further increased during the paroxysm, which is excited by various sensory impressions, sometimes exceedingly trifling, as a breath of air or the contact of a dress, a footfall, or the slamming of a door. The muscles of the trunk contract more strongly, and if the patient be on his back, the body may be so bowed that only the back of the head and heels touch the bed—*opisthotonos*; or the side of the face and leg, producing *pleurosthotonos*; or the abdominal muscles may bend the body forward—*emprosthotonos*. Spasmodic closure of the jaws sometimes causes the tongue to be bitten. The paroxysm may then relax, and during its relaxation the patient will be able to walk about. In severe cases the spasm may involve also the muscles surrounding cavities, as the thorax, compressing as in a vise their contents, causing extreme pain. Indeed, *pain* is almost everywhere an accompaniment of these spasmodic contractions, and the perspiration stands out in great drops on the face and covers the body. An attempt to speak is transformed into a fit of crying. The frequency of the spasms varies greatly; they may occur every couple of minutes or almost incessantly or once in several hours.

The temperature is generally, but slightly, if at all, elevated, rising to 101° F. (38.3° C.) and more rarely to 102° F. (38.9° C.). At times, however, it rises higher, to 105° to 106° F. (40.5° to 41.1° C.), and it is said also in fatal cases to reach 108° to 110° F. (42.2° to 43.3° C.). In a case reported by Joseph P. Tunis † it fell as low as 96.6° F. (35.5° C.), reaching a maximum of only 101° F. (38.3° C.). The *pulse* is generally frequent, 130 to 150, *respirations* 30 to 45. There is often *constipation*, which is a more serious symptom in severe cases, because the efforts to relieve it are apt to bring on spasm. Among the rare events have been the rupture of muscles and spasmodic closure of the glottis, producing fatal asphyxia. Generally, death is produced by exhaustion, the mind remaining unclouded throughout.

Diagnosis.—Tetanus is liable to be confounded with strychnin poisoning, cerebrospinal meningitis, and hydrophobia. *Strychnin poisoning* differs from tetanus in the absence of rigidity between the paroxysms and of trismus, and in the more marked involvement of the extremities, as well as the history of the case. In hydrophobia there is no trismus, and while convulsive dysphagia occurs sometimes in tetanus, it is very rare. As in strychnin poisoning, too, the individual paroxysms are more distinct.

Cerebrospinal meningitis produces a rigidity similar to that of tetanus, but the cerebral symptoms give it its stamp, and fever is a much earlier

* "Philadelphia Med. Times," vol. i., 1871, p. 418.

† "Archives of Gynecology and Pediatrics," April, 1892.

symptom than in tetanus. The stiffness of the jaws in *parotitis* and severe *tonsillitis* is similar to that of tetanus, but there the resemblance ends.

The interesting and rare condition known as *tetany*, or intermittent tetanus, characterized by the paroxysmal tonic contraction in groups of muscles, more frequently in the extremities, is hardly likely to be confounded with tetanus.

Prognosis.—The prognosis of traumatic tetanus is exceedingly unfavorable, not less than 80 per cent. perishing, while in the idiopathic form less than one-half die.

In children the prognosis is more favorable than in adults, and some very severe cases get well. The case of Joseph P. Tunis, already referred to, is a truly remarkable one of recovery in a boy six years of age after seventy days' duration. Most cases die within the first six days, and cases living to the sixth day are very much more apt to get well; the aphorism of Hippocrates, that "such persons as are seized with tetanus die within four days, or if they pass these they recover," is frequently substantiated. On the other hand, a late onset makes a case more hopeful. Localization of the spasm to the muscles of the face, neck, and jaw is favorable to recovery, and the so-called Rose's head tetanus most commonly gets well. The cases in which there is very little elevation of temperature are more apt to do well. Convalescence is likely to be protracted even in mild cases.

Treatment.—Prompt local treatment is important, though it is not often thought of until the mischief is done. The wound should be excised and cauterized by the hot iron or nitrate of silver, and antiseptic dressings should be applied. The patient ought then to be secluded and surrounded by the utmost quiet. After such seclusion Gacelli recommends the subcutaneous injection of a two per cent. solution of carbolic acid every two or three hours. He claims that carbolic acid gives better results than the antitoxin by antagonizing the toxin and quieting the nervous system. There are many difficulties in the way of the *antitoxin treatment* of tetanus in human beings, and it has perhaps been a disappointment up to the present time. The amount needed in proportion to the body weight increases enormously with the stage of the disease, in consequence of its extremely rapid production by the bacilli—millions of times, where diphtheria antitoxin increases but tenfold. Twenty to 30 c. c. of the fluid serum should be injected early, and 15 to 20 c. c. every five or ten hours. Of Tizzoni's solid antitoxin 2.25 grams should be the first dose, and 0.6 gram afterward at about the same interval—*i. e.*, 5 to 10 hours. The use of antitoxin in no way precludes the employment of spinal anti-spasmodic remedies, such as chloral, bromids, morphin, eserine, etc.

The further treatment of tetanus must be the treatment of the symptoms. *Morphin* is indispensable to control the pain and defer the paroxysms or diminish their severity, and anesthesia by ether or chloroform may be required during the paroxysm. The milder sedatives, like chloral, may suffice in mild cases, but they are insufficient in severe ones. *Chloral* may be used as an adjuvant in not less than 15-grain (1 gm.) doses for adults when the quantity of morphin otherwise required would be excessive. Even larger doses of chloral than those named may be given in connection with the antitoxin treatment. Subdural injection through a trephined opening is recommended by A. E. Barker,* who injected 7.5 c. c. of antitoxin at one time, and 20 c. c. subcutaneously daily for the following four days. In addi-

* "Philadelphia Med. Jour.," December 8, 1900.

tion massive doses of chloral were given. A week later the rigidity commenced to diminish, and in the course of three weeks the patient had completely recovered. The efficiency of chloral is also increased when combined with double the dose of bromid of potassium. To a less degree phenacetin, antipyrin, and antifebrin may be useful. Salicylic acid in large doses has been thought to be of value.

Reasoning from its physiological action on the nerve-centers, *calabar bean* ought to be a useful remedy, and it is commonly used in doses of 1-4 to 1-2 grain (0.0165 to 0.033 gm.) three to five times a day. *Curare* should also be useful for its sedative effect on the terminal nerves, but experience has not confirmed expectation as yet; 1-25 grain (0.0026 gm.) may be given hypodermically and cautiously increased. The strength of curare varies greatly. *Warm baths* are serviceable in relaxing spasm and often very comforting to the patient.

The most nourishing food in liquid form is necessary, and usually, also, stimulants are freely administered in tetanus, with a view to sustaining the patient against the exhaustion that sooner or later causes death unless the disease is arrested.

ANTHRAX.

SYNONYMS.—*Malignant Pustule; Contagious Carbuncle; Splenic Fever; Splenic Apoplexy; Gangrene of the Spleen; Carbuncle Fever; Blood-striking; Choking Quinsy and Bloody Murrain; Wool-sorter's Disease; Rag-sorter's Disease.* In France it is known as "*Charbon*," and in Germany as "*Milzbrand*."

Definition.—An acute infectious disease of animals, especially affecting cattle and sheep, but transmissible also to man; caused by the implantation and multiplication of the bacillus of anthrax.

History.—Anthrax was known to the ancients as a destructive disease of animals. The true poison was not, however, discovered until Pollander found it in 1855. Two years later Brauell also found it independently. Davaine, in 1863, greatly extended our knowledge of the whole subject by discovering the bacillus and inoculating many animals, including mice, rats, guinea pigs, cows, sheep, goats, and birds, and more recently Louis Pasteur and Robert Koch, 1878-81, studied the bacillus exhaustively from the biological standpoint. It was the first micro-organism recognized as the cause of an infectious disease. Mention should be made of Toussaint, who was the first to produce immunity by the use of sterilized cultures. His paper on "*Immunity from Anthrax Acquired as a Result of Protective Inoculations*" was published in the "*Proceedings of the French Academy of Sciences*," July 12, 1880. The disease is found all over the world. A number of cases occurred in Dubois, Pa., in 1897, by infection from hides imported from China.

Etiology.—The bacillus of anthrax, the largest of the pathogenic bacilli, is a minute cylinder 5 to 20 microns in length and 1 to 1.25 microns in breadth. It is found in enormous numbers in the blood and tissues of the animal infected with anthrax, where it multiplies rapidly by division. In artificial cultures it grows in long threads, in the interior of which appear minute ovoid spores, which are loosed by disintegration of the bacilli, which have but a transient existence, while the spores are very tenacious of life. Their vitality may remain in abeyance for long periods of time, and revive with the return of favorable conditions of heat and moisture. Introduced into the blood of animals they develop into bacilli. The medium of their

transfer to others, including human beings, is the blood, secretions, flesh, and hair from those infected. Here, as in glanders and hydrophobia, an abraded surface is necessary for successful inoculation, although the possibility of absorption through intact mucous membrane and skin is asserted. Those most frequently infected are herdsmen, stable-hands, butchers, and wool-sorters.

It is thought that anthrax bacilli may exist elsewhere than in animals, as in marshes and on the banks of streams, whence they may be carried by freshets into pastures and so infect grazing animals. Commonly, however, the affection spreads from other animals having the disease. Pasteur has found the bacilli in the herbage over the buried bodies of animals dead of the disease. It is primarily a disease of herbivora, from which it is transmitted to carnivora and man.

Hoffa has isolated a toxin, which he calls *anthracin*.

Morbid Anatomy.—The body after death is cyanotic. The blood is dark and viscid, coagulating slowly; the spleen is enlarged and soft. On the skin are carbuncular and gangrenous patches, the subcutaneous tissue is infiltrated with bloody serum, the blood is uncoagulated, and all the tissues and organs are more or less infiltrated with blood. The gastro-intestinal mucous membrane is edematous and ecchymotic, there are enlarged follicles and gangrenous patches infiltrated with bacilli, constituting the so-called *carbuncle of mucous membrane*. Even the nervous tissues are the seat of analogous lesions.

Symptoms.—Anthrax has a *period of incubation* of about seven days, after which there are a number of modes of manifestation of the disease, of which the chief are *external anthrax* and *internal anthrax*.

EXTERNAL ANTHRAX manifests itself as *malignant pustule* and *malignant anthrax edema*.

1. *Malignant pustule* starts most frequently on exposed surfaces of the skin,—the arms, hands, or face,—at the seat of inoculation. It begins as an *itching* and a *burning, smarting pain*, resembling often that from the bite of an insect. The spot becomes red and develops rapidly into a *papule*, in the center of which a *vesicle* soon appears, which is filled with clear, or at times bloody, serum. The vesicle bursts, the papule enlarges and becomes indurated, surrounded by a number of small vesicles. The induration extends, while the center becomes dark and discolored. Within thirty-six hours a brown eschar makes its appearance and rapidly undergoes disintegration. The vicinity becomes edematous, the lymphatics inflamed, swollen, and painful.

To these local symptoms are added those of *general infection*, with its thirst, high temperature, and frequent pulse. The tongue becomes dry, the liver and spleen enlarged, the breathing rapid, and death supervenes in from three to five days.

Occasionally, recovery takes place, but it is only in mild cases, in which all the symptoms, local and general, are less severe, that the vesicles dry up into a crust or scab, and the induration dies away.

2. *Malignant anthrax edema* begins in the eyelids and passes thence to the head, hands, and arms. The skin reddens and becomes edematous, vesicles may arise, but there are no papules, although the edema may proceed to extensive gangrene. The local symptoms in this form follow rather than precede the constitutional disturbance, as in the papular form, and the termination is even more invariably fatal than in the latter.

Anthrax presents an interesting contrast to hydrophobia in the absence of the anxious mental condition so characteristic of the latter.

INTERNAL ANTHRAX manifests itself as *mycosis intestinalis* or intestinal anthrax, and *pulmonary anthrax*. The latter is also called *wool-sorter's* disease.

1. *Intestinal anthrax*, or *mycosis intestinalis* is often ushered in by chill followed by nausea, vomiting, bloody diarrhea, and abdominal pains and tenderness. In addition to these symptoms pustules may form on the skin. It arises from the ingestion of meat infected with anthrax.

2. *Wool-sorter's disease* is a form of internal anthrax acquired by inhaling the bacilli into the lungs by those engaged in sorting wool, especially that imported from Russia and South America. It begins with chill, fever with high temperature, pain, dyspnea, bronchitis, and cough, together with the physical signs of lung involvement. There are rarely premonitory symptoms and often no external lesion. It is rapidly fatal, the patient often dying in twenty-four hours in collapse. Other cases are more protracted, and there may be vomiting, diarrhea, delirium, and unconsciousness, while the brain may be the chief seat of involvement, the capillaries being filled with bacilli. *Rag-picker's* disease is a special etiological variety, invading the lungs and pleura, with general infection.

Diagnosis.—The diagnosis of external anthrax is usually easy from the symptoms, in connection with the history of exposure to the cause. The fluid of the pustule may be examined for the bacilli, which are large and easily recognized. Cultures may be made and a mouse or guinea pig inoculated.

Internal anthrax is more difficult of recognition and may escape it altogether unless a knowledge of the occupation of the patient suggests it.

Prognosis.—The prognosis is unfavorable; yet not all cases perish. The intestinal form and wool-sorter's disease are especially fatal, though it is said also that those who survive the latter one week recover.

Treatment.—Prophylaxis is exceedingly important. Animals dead of the disease should be cremated—burying is not a safe plan; their hides should not be used; infected pastures should be shut off; disinfectants should be freely used in the wake of the disease. Hides, wool, and rags should be disinfected by superheated steam. In the case of wool and rags this is quite possible, but the necessary temperature is so high that hides are damaged by it.

The curative treatment consists in a vigorous attack on the seat of the infection. *Deep crucial* incisions should be made, and to these the actual cautery or caustic potash or strong carbolic acid should be applied and the wound dressed with a strong solution of carbolic acid, 1 to 20; or powdered bichlorid of mercury diluted with calomel powder, 4 to 15 per cent., may be thrown into the bottom of the incisions. As the sublimate dissolves it deepens the cauterization. The treatment is very severe and etherization may be necessary. Cocain at least should be freely used. In the edematous form numerous free incisions should be used and treated as the cuts into the carbuncle.

With the local treatment should be associated *stimulating and restorative measures*, including alcohol, highly nutritious food, quinin, and strychnin. Five to ten grains of ipecacuanha powder every three or four hours are recommended by Davies-Colley.

Internal anthrax must be treated by the general measures just alluded to, but is generally incurable. Free purgation is advised at the outset, with a view to removing the infecting material.

GLANDERS AND FARCY.

SYNONYMS.—*Farcy*; *Malleus humidus*.

Definition.—Glanders is an infectious disease more especially of the horse, communicable to man and certain domesticated animals, but not to cows; characterized by nodular growths in the nares, when it is known as glanders, and under the skin, when it is called farcy. Among animals to which it is communicable are the lion, sheep, rabbit, guinea pig, cat, dog, and mouse.

Historical.—Glanders was apparently described by Aristotle (B. C. 384–322) as occurring in the ass. It is first mentioned under the name μάλλος and *malleus* by Apsyrthus, a veterinary surgeon under Constantine the Great (A. D. 272–337), who, however, included under this name a number of affections of a more or less similar nature, and we are indebted for our first accurate knowledge of the disease to Rayer, whose monograph appeared in 1837.

The contagious nature of glanders was recognized by Soleysal (1664), Garsault (1741), and by the two writers Lafosse (1754–72); its inoculability and fatal character were demonstrated by Abeldgaard in 1795, while its contagiousness was experimentally established by Viborg (1797). Notwithstanding these facts, its contagiousness was long contested in France, and it was not until the middle of the present century that finally it became generally acknowledged in that country, chiefly through the labors of St. Cyr. Lorin in 1812, Waldinger in 1816, and Veith in 1822, made researches on the injurious effects of the virus on man. Schelling, of Berlin, was the first to give an exhaustive description, in 1821, of the disease as it occurs in man.

Etiology.—Glanders and farcy are the direct result of a bacillus—the *bacillus mallei*—described by Loeffler and Schütz in 1882. It is a short, non-motile bacillus not unlike that of tubercle and leprosy, but shorter than either. It is commonly seen among the cells of the growth, but has also been found in the blood. The disease is communicated through the discharge from the infected animal to an abraded skin surface or intact mucous membrane. The human victims are usually hostlers or others working about horses.

Morbid Anatomy.—The infection presents itself in the shape of nodules ranging in size from that of a lentil to that of a fist, or it may infiltrate more diffusely. It is composed of round cells which invade the skin, mucous membrane, and muscles. Internal organs,—as the lungs, liver, spleen, kidneys, and even stomach, the nervous system, bone, and cartilage—may be invaded. The ulcers on the skin are often serpiginous, whence the name *Wurm* among Germans. A few of the cells develop into epithelioid cells, but all soon break down, leaving ulcers on mucous membrane and skin, and abscesses under the latter.

Symptoms.—Glanders and farcy have a *period of incubation* of from three to five days, rarely a week. There is an *acute* and *chronic* form. The acute terminates within three weeks, while the chronic may last for months and even years.

In *acute glanders* of the nasal mucous membrane there is, first, *redness* and *swelling* at the point of inoculation with *burning* and *dryness* of the adjacent mucous membrane. *Intense pain* in the forehead from involvement of the frontal sinuses may also be present. This is promptly followed by nodule-formation and the rapid breaking down of the nodules and discharge of fetid hemorrhagic or muco-pus. The destructive process extends to the nasal septum, the mouth and pharynx, and even the larynx, lung, and other organs. The submaxillary glands swell and suppurate. From these lesions result the usual symptoms of *painful deglutition*, *cough*, and *hoarseness*, with *fetid expectoration*.

Chronic glanders is less easy of recognition. The symptoms are more like those of incurable coryza and sometimes of chronic laryngitis. It may be necessary to make cultures and inoculate an animal, preferably the guinea pig, which perishes in thirty days and presents already testicles swollen and suppurating.

In *acute farcy*, after the *period of incubation*, a *feverish state* develops. At the point of infection on the skin there appears a *nodular swelling*, or an ulcer which tends to spread and discharge a fetid hemorrhagic pus. The adjacent tissue becomes red and edematous and the lymph-vessels and lymphatic glands are inflamed. Papules that become pustules may also develop in the neighborhood. Such an eruption has been mistaken for that of smallpox, but is soon replaced by open ulcers. The so-called *farcy buds* are nodular, subcutaneous enlargements along the course of the lymphatics, and may supurate. The nose is not involved.

In *chronic farcy* the localized tumors form under the skin, especially of the extremities, and break down, but the process is more slow, and there is no special involvement of the lymphatic glands.

Further symptoms in both forms are: *chilliness*, *fever* with high temperature, *intense prostration* and depression, muscular and joint *pain* and soreness, *abscess* formation, and finally *typhoid symptoms* and death.

The *spleen* and *liver* may be enlarged, *albuminuria* may be present, and it is said even *leucin* and *tyrosin* are found in the urine.

Diagnosis.—The diagnosis in the acute form is easy. It has, however, been confounded with pyemia and smallpox. Chronic glanders is to be distinguished from syphilis and tuberculosis. The history of exposure is helpful. In doubtful cases cultures should be made. Especially characteristic is that on the cooked potato, which by the third day furnishes an amber-hued film, that on the sixth to eighth day is red and turbid, surrounded with a pale-green area. Inoculation with "mallein," a product of the bacillus of glanders, comparable to the tuberculin of tuberculosis, should be made. It causes a rise of temperature in affected cases as do tuberculosis cases with tuberculin. A reaction of 3.50° F. (2° C.) in horses is regarded as positive proof of the presence of the disease; a rise of 1.85° F. (1.5° C.) is strong presumptive proof, and 1.25° F. (1° C.) suspicious.

Prognosis.—The prognosis in the acute variety is invariably fatal; in the chronic form 50 per cent. recover.

Treatment.—In the cutaneous form excision and cauterization should be practiced as early as possible, followed by antiseptic dressings. In the nasal variety sprays of carbolic acid and bichlorid of mercury and peroxid of hydrogen should be introduced into the nose and throat. "Mallein" has also been used internally as a remedy, but its value is not as yet determined.

ACTINOMYCOSIS.

SYNONYMS.—*Big Jaw; Swelled Head; Bone Tumor.*

Definition.—An infectious inflammatory disease of cattle, communicable also to man, and depending for its existence on a peculiar fungus named by Hartz, a Munich botanist, *actinomyces* or ray-fungus.

History and Etiology.—The great German surgeon, Langenbeck, was the first to discover, in 1845, that the disease, "big-jaw," previously well known in the slaughter-houses of Germany, could be communicated to man. His results were not, however, published until 1878, a year after Bollinger discovered that it was due to a fungus.

Bollinger took it to Hartz, who gave it its name. The same year, 1877, James Israel, of Berlin, found the fungus in man, but did not recognize it as identical with the Hartz fungus. It was reserved for Ponfick, in 1879, to establish thoroughly the identity of the disease in man and in cattle. Belfield, of Chicago, first recognized the parasite in cattle in this country. Henry F. Formad and George A. Bodamer first studied the disease in Philadelphia, and through them I was able to examine specimens of the swelled-head from the slaughter-houses of that city.

The fungus belongs to the species *Cladothrix*, and is known as the ray fungus. As found in the pus from man and cattle affected with the disease, it appears as a small, yellowish granule from one to two millimeters ($\frac{1}{8}$ to $\frac{1}{4}$ inch) in diameter, detectable by the naked eye. By the microscope the granule is resolvable into conical threads, radiating from a center to which they are attached by their small ends, the other club-like ends being outward. This gives the external surface a mulberry appearance. The center is composed of a granular substance, containing numerous bodies resembling micrococci. The disease has been reproduced by inoculation of the fungus from a diseased animal, as well as by the inoculation of cultures. It is thought to arise primarily in animals in the course of their feeding on vegetable matter. This is the more reasonable, because the ray-fungus has been isolated from vegetables. A similar origin is ascribed to it in man.

The effect of the parasite is to produce granulomatous and fibromatous new formations, which ultimately become the seat of suppuration. The former, like tubercle, is composed of small round cells, epithelioid cells, and giant cells. The fibrous matter consists of proliferated connective tissue about the granulation growth, expanding and enlarging the bone until it resembles an osteosarcoma, for which it was for a time mistaken.

The tendency to suppuration is more marked in man than in cattle, where the process is a more localized one. In man the disease runs its course with the formation of multiple abscesses and chronic pyemia. Such course is supposed to be due to an admixture of pyogenic organisms with the true ray fungus. Associated with the suppurative process in man is a tendency to fatty degeneration of the cells of the granulation tissue.

Morbid Anatomy.—In addition to the lesions presently to be described about the jaw and head, there are found in the lungs, when the latter are invaded, the miliary nodules alluded to, made up of groups of fungi, surrounded by granulation-tissue. Bronchopneumonic areas and abscesses large enough to be recognized by their physical signs during life may also be present. Erosion of the vertebræ, ribs, and sternum may also occur.

Symptoms.—The route of infection is generally the mouth, while the special seats seized upon are carious teeth, whence the *jaw* is invaded and becomes swollen. The swelling may extend thence to the face and temporal region, and even to the neck, producing *discharging sinuses* like those associated with dead bone. Alongside of these are cicatricial marks of healing. More rarely the tongue, fauces, and even the intestines (large and small), and the liver are invaded. The latter organ may also become involved metastatically. The fungus has been found in the stools first by Ransom, and pericecal abscess has been found due to it.

The *lungs* are also favorite seats of invasion by actinomycosis, and it was in these organs in man that Israel recognized the fungus which proved to be the ray-fungus also. The *symptoms* produced are *those of bronchitis*—fever, cough, and more or less fetid expectoration, in which the fungus is occasionally found. In the lungs the posterior and lateral parts are affected rather than the apices. They may be invaded simultaneously with the jaws. The course of lung actinomycosis is chronic, and resembles that of pulmonary consumption, the average duration in man being ten months.

Actinomycosis may occur in connection with the *skin* alone, and even in the *brain* abscesses may occur containing the mycelium. Bollinger has reported a case of the primary disease in the brain of man, while Gamgee and Delpine and O. B. Keller have found it in the brain secondary to pleural invasion. The metastatic abscesses are the direct result of the transfer of a portion of the fungus.

Diagnosis.—*Sarcoma* of the jaw presents a macroscopic picture very

like that of actinomycosis, but its course is more rapid and there is less suppuration, yet these signs are of themselves insufficient, and the recognition of the fungus may be necessary to a diagnosis.

More frequent, perhaps, than any other error is that which mistakes the disease for *pyemia*, of which, indeed, as it occurs in man, it is a chronic variety. There are the same sort of metastases in the lungs and elsewhere; in man with pus formation, in animals with or without slight suppuration.

Treatment.—The treatment is surgical, consisting in thorough extirpation, the opening of the abscesses and removal of the dead bone, followed by thorough drainage. Iodid of potassium in doses of 40 to 60 grains (3.66 to 4 gm.) was recommended by Thomassen in 1885, and cures are reported from its use. Da Costa also reports success with this drug.*

FOOT AND MOUTH DISEASE.

SYNONYM.—*Aphtha epizooticæ*.

Definition.—An acute infectious disease of lower animals, especially of cattle, sheep, swine, more rarely the goat and horse, and still more rarely of fowls, dogs, and cats. The disease in cattle spreads rapidly and entails often serious loss. It is characterized by fever and the presence of vesicles and ulcers in the mucous membrane of the mouth, in the furrows and clefts about the feet, and on the teats of animals. It is communicable to man, especially during epidemics.

History and Etiology.—The early confusion of foot and mouth disease with anthrax and actinomycosis makes it difficult to date its first recognition. Hertwig, however, established its contagiousness as early as 1834 by experiments upon himself and two other men. The experiments consisted in the drinking of infected milk. Local and constitutional symptoms of the disease resulted.

The microbe responsible for foot and mouth disease has not been settled upon, though a streptococcus has been isolated from the fluid of the vesicle by Klein, and a micrococcus from milk by Cnyrim and Libberitz; the specific power of neither has as yet been determined. The contagion bearer is especially the contents of the vesicle alluded to, but milk, blood, and urine and feces are also media. It is communicated to man through the ingestion of unboiled milk, butter, and cheese, or through contact with the fluid of the vesicles on the teats by milkers. It is said to be communicable even by the saliva from the affected animal.

A certain relation is believed to exist between the aphthous sore mouth of children and the foot and mouth disease, chiefly because it has been observed that aphthæ are apt to prevail in children at the same time with the foot and mouth disease in cattle.

Morbid Anatomy.—As recovery invariably takes place, no lesions other than those to be noted under symptoms have as yet been observed.

Symptoms.—The disease has a *period of incubation* of from three to five days. At this time there is a *febrile movement* with *malaise* and *loss of appetite*. On the mucous membrane of the lips and tongue, and sometimes on the hard palate and pharynx, come *vesicles* containing a yellowish serum. There is a sensation of *heat* and *burning* throughout the mouth, and the *swelling* may be so great as to make speech difficult and swallowing painful.

* "Proceedings of the Association of American Physicians," 1900.

There is *copious salivation*. Almost simultaneously appear vesicles between the fingers and toes and around the nails. Vesicles have also been noted on the nipples of women. Indeed, they have been found scattered all over the body, so that the case resembles smallpox. The hands, especially, may be extensively involved. Gastro-intestinal symptoms are sometimes present.

Prognosis.—The prognosis is favorable in man, recovery being the rule. Very young children may perish. The suckling young of animals perish in large numbers, because of the infected milk on which they subsist.

Treatment.—The disease can be easily avoided by simple prophylactic measures by those in contact with animals, of which the use of boiled milk is the most important. Cleanliness of man and beast conduce to the same end.

Curative measures of a simple kind generally suffice. Mouth-washes of a saturated solution of chlorate of potassium should be frequently used. Powdered borax and alum may be directly applied. The separate ulcers or vesicles should be touched with the solid silver nitrate. The skin lesions should be washed in corrosive sublimate solution and dressed in sublimate cotton or salicylated cotton. The fever should be combated with suitable antifebrile measures.

MILK SICKNESS.

SYNONYMS.—*Trembles; Puking Fever; Slows.*

Definition.—An infectious disease prevailing in the western and southwestern parts of the United States, characterized especially by trembling, vomiting, constipation, and a peculiar fetor of the breath.

Etiology.—A like disease prevails among the cattle of the infested districts, and it is supposed to be communicated to man through the milk and its products—viz., cheese and butter, and also flesh when used as food. It is more common in summer and autumn and in dry seasons. Nothing more definite is known as to its cause.

Morbid Anatomy.—Our knowledge of the morbid anatomy of milk fever is chiefly by inference from that obtained by necropsies on cattle, those on man being few and imperfect. The lesions noted by Grof under these circumstances are as follows: Cerebral sinuses, meningeal vessels of the brain and cord distended with blood; pia mater opaque and overlaid with purulent exudate; brain soft; stomach and intestines contracted and mucous membrane injected; lungs, liver, kidneys, and spleen engorged with blood, the liver and spleen soft, the latter enlarged in some cases to twice the normal size, the blood fluid.

Symptoms.—There is usually a *prodrome* of two or three days, manifested by simple *uneasiness* and *discomfort*, after which the disease is usually ushered in suddenly by severe epigastric *pain*, *constipation*, *nausea*, and *vomiting*. Hence the term “puking” sickness. There is also moderate *fever* and disproportionate *thirst*. The *pulse* at first is full; later, small and rapid. There is marked *tremor* or muscular twitching on attempt at motion. The constipation is characteristic. The tongue is swollen and the breath is peculiarly foul. This is said to be diagnostic. A typhoid state may supervene, preceded by restlessness, irritability, coma, and even convulsions.

Prognosis.—The duration of the disease is from two to ten days or longer. The short cases are the fatal ones. When recovery takes place, convalescence may be protracted three to four weeks.

Treatment.—The treatment is symptomatic, and consists chiefly in

combating by alcohol, aromatic spirits of ammonia, and food the tendency to weakness. Happily, the disease appears to be dying out as land is improved.

Prophylaxis may be secured by fencing off cattle affected and carefully guarding against the use of infected food and milk.

SYPHILIS.

SYNONYMS.—*Lucs venerea*; *The Pox*.

Definition.—Syphilis is a specific constitutional disease of human beings, due to inoculation by a special virus or to hereditary transmission characterized by a tendency to a localized deposit of various inflammatory new formations. Under the former condition it is known as *acquired syphilis*; under the latter, as *hereditary syphilis*. It is apparently confined to the human race.

Historical.—Syphilis was first described as a separate form of venereal disease in 1494, when it prevailed as an epidemic among the troops of Charles VIII before Naples. Thence it spread over Italy into France, Germany and the rest of Europe. As this was immediately after the discovery of America it has been alleged that the disease was introduced into Europe from America, and it has also been claimed that it was introduced from Africa. In fact, we have very little definite knowledge on the subject, but there seems good reason to believe that the disease is much older than the dates given.

Etiology.—In common with all infectious diseases, syphilis is ascribed to the operation of a bacillus, and two or three have been selected as responsible and then abandoned. The latest is that described by Lustgarten in 1884. It resembles the tubercle bacillus and leprosy bacillus, is slightly clubbed at the ends, and from three to four microns in length. Matterstock, Travel, and Alvarez claim that it is not differentiable from a similar bacillus found in preputial and vulvar smegma. It is said, however, to be distinguishable from the smegna bacillus by the carbofuchsin test. Cultures of the bacillus of syphilis have not as yet been successful, and it must be admitted that there is still much doubt on the subject.

Syphilis is one of the most highly contagious diseases. In the first place, the blood of the syphilitic is inoculable and capable of producing the disease. Further, the secretions of all primary and secondary lesions of the skin and mucous membranes are similarly potent. The products of the third or gummatous stage are not so regarded, although opinions are not unanimous on this point. A raw or abraded surface is a necessary condition of inoculation. The physiological secretions, such as the tears, milk, nasal and bronchial mucus, do not communicate the disease when inoculated, although they may become virulent by contamination with the poisonous secretions. Exceptions to this law are the spermatozoid of man and the ovule of woman, each of which, if derived from a syphilitic source, is capable of infecting the other.

The acquired disease has three stages—a *primary*, *secondary*, and *tertiary*. The *primary* is characterized by a primary sore associated with glandular enlargement in the neighborhood of the seat of inoculation. The *secondary* stage furnishes lesions of the skin and mucous membranes, among which sore throat is especially conspicuous. It is sometimes accompanied by fever. The *tertiary* is characterized by affections of deep-seated structures, the osseous and nervous systems, the liver, spleen, kidney, and testicle; also the subcutaneous and submucous tissues.

The initial sore makes its appearance within six weeks after exposure, usually in two or three weeks. The phenomena of the second stage usually show themselves within three months or from six to twelve weeks. The

third stage is more difficult to define by temporal limits. It is by years rather than by months, and is characterized, as stated, by the involvement of the deeper-seated organs. Hereditary syphilis, when not present at birth, makes its appearance within the first three months; after six months the child may be regarded as safe.

In the vast majority of cases, acquired syphilis comes from sexual intercourse, but it may be the result of contact in many ways, as by the lips, teeth, infected hands, and other parts of the body. Drinking-cups, utensils, and other articles used by the infected in common with others, sometimes convey the infection. Physicians are not infrequently infected in midwifery practice, the initial lesion making its appearance around the nail or in the web between the first and second fingers. Wet-nurses acquire the disease from syphilitic nurslings, the chancre occurring in a fissure or abrasion of the nipple. Vaccination has in rare instances been a means of infection.

Heredity syphilis may be transmitted through the father or the mother. In the former instance it is called *sperm inheritance*; in the latter, *germ inheritance*. Syphilis may be communicated by the father while the subject of the active disease, or after all signs of it have disappeared. On the other hand, a syphilitic father may beget healthy children. The question has sometimes to be decided by a physician as to whether a syphilitic, apparently recovered, may marry with safety to offspring. It will be seen from the above that an absolute answer dare not be given; but this much may be said, that the longer the interval since the primary attack the less likely is the offspring to be tainted, and it is generally acknowledged that systematic and continuous treatment may eliminate the disease altogether. An interval of not less than three years should be insisted upon between the disappearance of the last symptom and the patient's marriage. It is to be remembered also that each successive child of syphilitic parents shows less signs of the disease, until finally healthy offspring results.

A syphilitic mother may, of course, bear syphilitic children from germ infection, producing thus true hereditary syphilis; but a child may also be infected at the moment of its birth, when the syphilis is congenital but not inherited. On the other hand, a woman may bear a syphilitic child, and, though herself without signs of the disease, will not, according to Colles's law, be infected by her child should she suckle it while it has syphilitic ulcers of the lips and tongue. Yet a healthy nurse who suckles this same child, or merely handles and dresses it, may be infected. Such a woman is supposed to have received protective inoculation without evident signs of the disease; and we may have here an example of protection through a natural antitoxin absorbed from the syphilitic fetus by its non-syphilitic mother.

A woman may be infected after conception, when the child may be born non-syphilitic or syphilitic by placental transmission.

Of course, when both father and mother are infected, the chances of the offspring being infected are doubled.

Morbid Anatomy.—I. *Of Acquired Syphilis.*—At least five sets of lesions may be traced to acquired syphilis. The *first* is the initial lesion, the chancre or primary sore at the point of inoculation and usually two or three weeks afterward. This constitutes primary syphilis. Beginning as a wounded or abraded spot, a vesicle or papule develops, which subsequently softens in the center and forms an ulcer with a hard, grisly base and edge, constituting the hard or indurated chancre. It is found to consist in a dense infiltration of small cells, some of which develop into large formative

(epithelioid) cells and others even into giant cells, but no further differentiation takes place; for the most part the infiltration breaks down and is absorbed, a few of the cells going to form the cicatrix. In the broken-down tissue is found the Lustgarten bacillus. The chancre is found usually in males on some part of the penis, especially on the prepuce, and in females on the labia or vaginal part of the cervix. It may be so small as to escape notice, especially when within the urethra. The sore lasts from three or four weeks to as many months. Its peculiar induration is easily recognized by taking it up and pinching it between the fingers, though it is often not characteristic on the flat mucous membranes of the genitalia of women.

Along with the chancre there is a *second* lesion, an adenitis of the adjacent lymph glands, which may suppurate, forming a bubo, or there may be a hyperplasia of connective tissue, terminating in persistent induration of the gland. It usually appears simultaneously with the induration or soon after it is established. Buboës may be long stationary and are then said to be indolent. They may be multiple. They belong to the symptoms of primary syphilis.

The *third* lesion is the mucous patch, soft papule or *condyloma latum*, which is one of the events of the secondary stage of syphilis. It has its seat on mucous membrane or on soft, moist skin, as in the perineum, groins, between the toes, at the junction between the skin and mucous membrane at the angle of the mouth, and about the anus. It consists of an inflammatory infiltration of the epidermis and corium with small cells. A more highly differentiated infiltration of the papillæ of the mucous membrane is the acuminate condyloma, or *venereal* wart, especially common about the vulva and anus.

The *fourth* lesion is the cutaneous affection, or *syphilid*, of which there is a roseolar or macular, a papular, a pustular, a squamous, and a tubercular variety. All are characterized by a copper-colored hue, especially permanent after the other features have subsided, and a tendency to symmetrical distribution. The *macular* or roseolar syphilid affects more particularly the abdomen, the chest, and the front of the arms, while the face is exempt. This syphilid persists a week or two. The *papular* eruption is in groups on the face and trunk. The *pustular* eruption often closely resembles that of smallpox. The *squamous* syphilid resembles other squamæ, but it is especially distinguished by its coppery hue. It involves preferably the backs of the arms and the front of the thighs—the extensor surfaces—and is moreover rare. The skin syphilids are symmetrical in the early stages, but in the latest stages become irregular and unilateral in their distribution.

The *fifth* or remaining set of lesions constitutes the tertiary manifestation, and involves the deeper tissues, such as the subcutaneous tissues, the osseous and the nervous systems, the liver, lungs, and kidney. They include especially the *tubercular* and *gummatous syphilids* and fibroid induration. The first occur in single nodules or may coalesce to form a solid tubercular patch; also form serpiginous patches or segments of circles. They are confined to certain regions as a rule, face, back, and more rarely extremities, and are usually unilateral. The most general of these is the *fibroid induration*, consisting in a development of fibroid tissue like that of chronic inflammation. The new tissue thus formed arises around the blood-vessels, and consists, at first, of a small-celled infiltration, which later is converted into fibroid tissue. It is found also in the periosteum, the sheaths of the nerve trunks, the capsules, and interstitial tissue of organs and muscles. It occupies, for the most

part, small areas surrounded by normal, unaffected structures. When in the capsules of organs it sends prolongations into their interior, which partition off the organ and by their subsequent contraction give rise to irregular thickening and cicatricial puckering.

A differentiation of this fibroid change, a most characteristic lesion of syphilis, is the *gumma*, a yellowish-white fibrous nodule, closely continuous by its outer layer with the connective tissue of the organ in which it is imbedded. It varies in size from that of a pin point to three to five centimeters (1 to 2 inches) in diameter. Histologically, it is with tolerable ease separated into three parts—a central or oldest part in a state of atrophic cheesy degeneration, an intermediate layer of imperfect fibrous tissue, and an external layer of vascular granulation-tissue rich in cells. It is frequently associated with the fibroid change above described. In the degenerative changes to which the gumma is subject it may produce extreme destruction of the organ in which it is imbedded.

The seats of the gummy tumor are the skin, subcutaneous and submucous tissue, muscles, fasciæ, bone, where it forms the *sypilitic node*, the connective tissue of organs, especially the liver, brain, testicle, and kidney, less commonly the lungs. When in submucous tissues, it may give rise to deep-seated ulceration and suppurative processes, leading to destruction, not only of soft tissues, but also of bone. Especially frequent and repulsive in its result is the destruction of the nasal bones with perforation of the palate. The bacillus of Lustgarten is said to be found in the gummy tumor.

Another variety of deep-seated syphilids, *sypilitic rupia*, consists primarily of large pustules, which dry and crust over with laminated scabs, while beneath is a deep ulcer. This may subsequently heal, leaving a scar. Large pustular lesions and tubercular syphiloderms occur especially in the neighborhood of the sacrum.

Another tertiary lesion of syphilis, although probably not peculiar to it, is *sypilitic arteritis*, which consists in a cellular thickening of the vessel-walls, beginning in the intima and intruding thence on the lumen of the vessels. The outer coat is abnormally vascular and infiltrated with small cells that also invade the muscular coat. These are the phenomena of obliterative endarteritis, which have thus far been studied only in the vessels of the brain by Greenfield and Huebner.

Symptoms.—The symptoms of acquired syphilis are so largely the morbid states described under the head of morbid anatomy that most of them need only be enumerated in connection with the date of their appearance. The chancre or primary sore and the bubo, which together constitute primary syphilis, have been sufficiently described.

The secondary symptoms manifest themselves usually from the sixth to the twelfth week, but may be as late as three months. *Sore throat* is one of the first of these symptoms, and is commonly associated with *fever*, which rarely exceeds 101° F. (38.3° C.). It may be remittent and even strikingly intermittent, and in rare instances rises much higher than 101° F. (38.3° C.), reaching 104° F. (40° C.), and even 105° F. (40.5° C.). The sore throat alluded to is associated with hyperemia of the fauces, often with intractable gray-based ulcers, and less frequently, with mucous patches and syphilitic warts. The inflammation may extend from the throat into the Eustachian tube and middle ear, producing impaired hearing. The larynx is especially liable to become the seat of ulceration, which may heal and produce marked deformity.

Then there are the syphilids named. Along with these, a very common symptom is the *falling out of the hair*, and especially from the eyebrows, giving rise to a striking change in the facial expression. An inflammatory condition at the root of the nails, *syphilitic onychia*, causes them to become brittle and distorted. Other secondary symptoms not mentioned are *iritis*, and more rarely *choroiditis* and *retinitis*. The former presents itself in from three to six months after the primary chancre, and is one of the most painful and trying of symptoms, requiring prompt and energetic treatment. Involvement of the *car* ossicles is rare but possible, producing deafness.

Joint affections are sometimes associated with tertiary syphilis. These may, of course, result from the invasion of the joint ends of the bones by the gummatous syphilitic disease, to which they are subject, but there may also be direct involvement of the *serous* tissues themselves by inflammatory and gummatous processes that give rise to pain and interfere with motion. The *bone affections* of syphilis are characterized by nocturnal pains, said to be due to pressure from distended veins.

The involvement of internal *glandular* organs occurs later, ten or more years after the primary lesion, though precocious tertiary lesions of this kind have been reported much earlier. *Amyloid disease* is a very common tertiary affection, involving liver and spleen and producing some of the most striking enlargements of the former. But cirrhosis and cicatricial markings are also common. Syphilitic lesions of the liver are of such a degree and importance as to demand separate consideration under the diseases of that organ.

A *sarcocele* involving the whole testicle is among the tertiary affections often mistaken for tuberculosis, from which it may be distinguished by the fact that the latter is accompanied by tuberculosis elsewhere, and involves the proper structure of the testicle instead of the whole organ. *Sclerosis of the spinal cord* is frequently associated with syphilitic history, and it is often ascribed to it. A special condition is an involvement of the nervous system of such importance as to require a separate section. *Gummy tumors of the brain* occur, producing pressure symptoms; a similar association is true of *arterio-sclerosis* as well as the *arteritis obliterans* alluded to.

Sooner or later the syphilitic becomes anemic and an examination of the blood recognizes a reduction in the number of red corpuscles, in the hemoglobin and an increase in the white cells.

II. *Of Hereditary Syphilis*.—Except the primary chancre all the symptoms described as occurring in acquired syphilis may be present in the congenital form. It may be said, in a word, that visceral alterations are more prominent, especially those involving abdominal organs. It is necessary, therefore, to mention here only those that may be regarded as additional.

Among the most important of these is repeated *abortion*. It is very common to have four or five and even more abortions, while each successive one usually takes place longer after conception until finally a living child is born. Such aborted products are shriveled, the skin exfoliates, and there is often reason to believe they have been some time dead. Syphilitic children born at term have evidently been arrested in development, are shriveled and wizen-faced, and may suffer from cutaneous syphilids. The so-called *pemphigus neonatorum*, with blebs occurring about the wrists, hands, ankles, and feet, is characteristic. There is also apt to be enlarged liver and spleen. Or a child may be born apparently healthy and take on these symptoms after three or four weeks. Lesions of hereditary syphilis are reported as beginning even later than this, up to the sixth month. This is, however, unusual.

Rhinitis, or nasal catarrh with *snuffles*, is one of the earliest, to be followed by cutaneous lesions, particularly about the nates. *Fissures* about the lips and ulcerations on the muco-cutaneous surface are present, from which the discharges are inoculable.

Disease of the epiphyseal cartilages of long bones and of the cartilages of the ribs is a very common symptom of hereditary syphilis. The zone of the cartilage adjacent to the bone exhibits proliferated cartilage cells and prolongations over the end into the diaphysis instead of being sharply separated. There is *tendency to hemorrhage*. A *syphilitic cry*, high pitched and harsh, is described. To these may be added any of the symptoms already mentioned under acquired syphilis.

A later symptom is "notched teeth," first described by Jonathan Hutchinson as characteristic and distinctive of hereditary syphilis. The teeth affected are the permanent central incisors of the upper and lower jaws. The appearances are not uniform, and are better appreciated by examining the accompanying drawings than from descriptions. Other late symptoms are keratitis, iritis, impaired hearing from ear affections, periostitis, and splenic and hepatic enlargement.

If it survive the earlier lesions or escape them, the syphilitic child remains undeveloped and stunted in its growth, and in consequence of arrest of development a singular reversal of the appearance of premature age,

Fig. 18.—The lower incisors of a girl, aged fifteen, the subject of inherited syphilis. The teeth are very short, rounded, and peg-like, with wide interspaces. This set shows the most typical condition ever exhibited by the lower set—(after Hutchinson).

Fig 19.—The two upper and four lower incisors (permanent) of a girl, the subject of inherited syphilis, all recently cut. The upper teeth are narrow from side to side, at their edges, and show a thin middle lobe, bounded above by a crescentic line. The lower teeth are rounded and show foliated extremities. All the teeth are small and spaces occur between the adjacent ones. In the upper ones the crescentic thin mid-lobe, and in the lower ones the foliated extremities will, before long, break away—(after Hutchinson).

described as characteristic of the syphilitic child at birth, takes place. The new-born syphilitic child looks prematurely old. A popular novelist has aptly described the appearance of the syphilitic child in the terse phrase, "a little old man with a cold in its head." The syphilitic who outlives his childhood remains, however, younger looking than he actually is, insomuch that a young man of twenty may appear as though he were but twelve, a condition to which Fournier applies the name *infantilism*. In such the forehead is prominent, the frontal bosses are marked, the bridge of the nose is depressed, its tip turned up. The head may be asymmetrical.

Diagnosis.—The recognition of general syphilis is not difficult. The symptoms described are of themselves distinctive, and if there be added the history of exposure or heredity they are unmistakable. When there is doubt the administration of specific remedies will soon clear it up. In consequence

of the fever and frequently associated splenic enlargement with roseola, the second stage of syphilis has been confounded with typhoid fever. The pustular syphilid has sometimes caused its subject to be taken to a smallpox hospital, where, however, time soon dissolves all doubt.

The so-called "Justus test" is based upon the following proposition: Mercury destroys the hemoglobin of the blood. In the non-syphilitic subject, the organism rapidly replaces the lost pigment. In the syphilitic patient, however, the percentage being reduced by the disease, the organism cannot at once restore the still further reduction caused by the use of mercury. Consequently the first examination after an inunction or injection of mercury will show a distinct fall of from 10 to 20 per cent. This reduction is in turn followed as treatment is continued by a steady rise to the normal, where it remains as long as treatment is maintained.

Prognosis.—The prognosis of acquired syphilis depends wholly on the treatment. With early treatment properly conducted it is favorable; without treatment or with defective treatment the most serious consequences result, while the physical inconvenience and suffering scarcely exceed the mental misery which the knowledge of the presence of so loathsome a disease entails. In congenital syphilis treatment is less satisfactory for the severer manifestations, and it is perhaps fortunate that so many perish in infancy or early childhood. Even those most fortunate remain delicate and vulnerable to disease through life, and too often fall victims to causes which but slightly affect the healthy man and woman.

Treatment.—*Prophylaxis.*—Against sexual syphilis the only prophylactic measure to be relied upon is sexual purity. The duty of the physician is plain in respect to this, and the medical man who advises illicit sexual intercourse for any reason degrades his calling. Medical men should be exceedingly cautious in their necessary professional contact with all suspected of having syphilis and protect themselves against accidental infection. It is to be remembered that the secretions of all primary and secondary lesions, as well as the blood of syphilitics, may transmit the disease.

Treatment of the Primary Sore.—With the present view that the hard chancre, which makes its appearance after a *period of incubation* of a least two weeks, is simply the local expression of a general disease, nothing is gained by "burning it out." The indication is simply to heal the ulcer as thoroughly and as soon as possible. Fortunately, there is little difficulty in accomplishing this. A simple dressing, as lint wet with bichlorid solution 1 to 2000, or mercurial ointment smeared on adhesive plaster, with an uncovered edge so as to secure adhesion, will accomplish the healing in a short time. Iodoform, bismuth, calomel or acetanilid may be dusted over the sore.

The Constitutional Treatment.—This should begin at once. *Mercury* and *iodin* are the two remedies, and if properly used will eradicate the second stage and hold the third in abeyance, even after it has manifested itself. *Mercury* is the remedy *par excellence* of the *second stage*; iodid of potassium, of the *third*. The best method of administration for mercury is undoubtedly by *inunction*. The following is the plan to be pursued: A warm bath is taken, if possible, each day, and immediately thereafter one dram (4 gm.) of mercurial ointment is spread between the hands and rubbed, one day on the inside of one thigh, the next on the inside of the other; again, under the arm, on the chest, and so on until each part of the body covered by softer skin is treated, after which the same course can be repeated. The friction is to be kept up until the skin is thor-

oughly dry, half an hour being usually necessary. The part rubbed should be washed off the following day. Parts covered with hair are to be avoided, because mercurial eczema, characterized by pustules starting from the hair follicles, is more apt to be produced in these localities. During this time the patient should not smoke, and the teeth should be frequently and carefully cleansed and the mouth washed with solution of chlorate of potash with a view of averting mercurial sore mouth. Sooner or later, however, sore mouth may manifest itself by a fetid odor, swollen gums, and a sensation as though the teeth were loose, when the treatment should be suspended for a week or ten days. The daily friction should be kept up for thirty days, if possible, after which, if no symptoms are present, it may be discontinued.

The inunctions should be followed up by the use of protiodid of mercury, 1-4 grain (0.016 gm.) three times a day, or the biniodid, 1-16 grain (0.004 gm.) three times a day. The former is usually preferred because less irritating. This last addition to the treatment should be kept up indefinitely. By such means as these tertiary symptoms can be averted if the patient is but willing to continue the treatment. The great difficulty is to secure this. He tires of the monotony and the trouble involved in a faithful adherence to the directions, and symptoms sooner or later return. Should secondary symptoms recur a course of inunctions may be repeated.

In lieu of the inunction, the *hydrargyrum cum creta*, or gray powder, may be used. It is the favorite of Jonathan Hutchinson, who gives it in form of a pill, 1 grain (0.066 gm.), with 1 grain (0.066 gm.) of Dover's powder, from four to six times a day, and is commended by my colleague, Louis A. Duhring, who has used it with great success.

Again, the mercury may be administered by *fumigation*. For this the patient sits on a chair, wrapped in blankets to the chin, as in a tent. Under the chair is placed a spirit lamp and over this a tin plate on which calomel is spread. It is volatilized by the heat and deposited with the vapor on the patient's skin. The exposure should last *twenty minutes*, after which the patient should be put to bed wrapped in blankets, without washing or drying.

Most recently, mercury has been administered by direct *injection* into the muscles. One-third grain (0.0216 gm.) of bichlorid dissolved in 20 minims (1.333 c. c.) of water is injected once a week, or from 1 to 2 grains (0.066 to 0.132 gm.) of calomel in 20 minims (1.333 c. c.) of glycerin and water. The injection is made deep into the muscles, and not in the subcutaneous tissue, through silver cannulæ. The points selected are the sides of the thorax and back, where abscesses are said to be less likely to occur. Great care should be taken in sterilizing instruments. The nicest attention to these points is, however, still followed at times by abscesses.

In the treatment of the *third stage the iodids* are especially useful. It is here that massive doses of iodid of potassium are indicated and often produce such magical results. The most convenient mode of administration is the saturated solution, of which one drop contains a grain (0.066 gm.). Starting with 10 drops, a drop may be added each day to the dose until the symptoms yield, that is, until the gummy tumors melt away. Pressure symptoms and head and bone pains are relieved. The iodid is well administered in milk. The indications for its discontinuance or reduction in the dose are the erythematous rash, coryza, and salivation and constriction about the throat due to swelling of the salivary glands.

THE GONORRHEAL INFECTION.

Recent studies go to show that the gonorrhæal infection is scarcely less harmful and widespread in its effects than syphilis. These effects, formerly limited to the primary infection, the ophthalmia and gonorrhæal arthritis in men and women, have been found to be responsible for the vast majority of inflammatory pelvic troubles in women that make life a martyrdom and child-bearing an impossibility. The explanation of this appears to lie in the fact that a urethral discharge continues to be infectious long after it has lost its purulent character, and the only test of recovery from gonorrhæal infection is a bacteriological one. At least such is the inevitable conclusion after reading the able and exhaustive paper on "Gonorrhæa; its Dangers to Society" by Albert Neisser,* of Breslau. This is a startling statement, but should be proclaimed from the housetops if it will have any influence in preventing infected men from infecting innocent women whom they have married under the impression that they are free from disease.

These ills which have been referred to are largely surgical and do not concern us as physicians, for medical treatment is generally unavailing. One is, however, classed among medical ailments and will be here considered. It is—

GONORRHEAL ARTHRITIS.

Definition.—Gonorrhæal arthritis is a septic arthritis due to the gonococcus.

Morbid Anatomy and Pathology.—We do not often have an opportunity to study the morbid changes in the joints in this affection, since patients never die of this disease alone. Reasonably, however, we may expect a primary hyperemia, and later the phenomena peculiar to inflammation in similar structures—viz., exudation into the joint cavity, including the out-wandering of white blood-corpuscles, which are, however, rarely so numerous as to constitute pus. The periartritic tissues, including the sheaths of tendons, are invaded by the exudate, and pus has been found in these sheaths. There may be not only change in the shape, but impairment also in the motility of the joints. They may become stiff and swollen as in chronic rheumatism.

Now as to the nature of this disease. Gonorrhæal rheumatism is an affection in which symptoms identical with those of rheumatism are more or less closely associated with gonorrhæa. These rheumatoid symptoms usually appear from six to ten days after the discharge is seen. They may appear, however, much later—as much as four or five months or even a year after the discharge sets in, or during a chronic gleet. A lately married woman may acquire it from a husband who has gleet, indeed, as has been mentioned, after all visible objective signs of gonorrhæa have disappeared from him, though a bacterial examination may discover the gonococcus. There seems to be no relation between the severity of the symptoms and that of the original disease. The discharge, if present, generally continues with the onset of the joint symptoms, although it often abates, and may even cease altogether for a time. It may even recur with the disappearance of the

* "Medical News," January 13 and 20, 1900.

rheumatic symptoms. It cannot be said that the true relation between these two very definite conditions is exactly known. The term *gonorrhœal rheumatism* is very generally recognized in all languages, and some English and American physicians do not hesitate to speak of the disease as a species of rheumatism. This is certainly erroneous. It is doubtless caused by the gonococcus, which, when once present, seems to be ineradicable, though it may continue latent until conditions favorable for its activity arise. Witness its power to cause ulcerative endocarditis. The simple non-purulent synovitis and arthritis may be the result of absorption of ptomaines furnished by the urethral pus. These views are confirmed by modern bacteriological studies, which have found gonococci in the pus, in the tendinous sheaths, and more rarely in the non-purulent exudate.

Although the gonorrhœal poison is quite sufficient to produce the arthritis *de ipso*, it frequently happens that cold co-operates as an exciting or predisposing cause.

Gerhardt found that out of 928 cases of arthritis 7.43 per cent. were gonorrhœal, while Gricolle found that out of 4423 cases of gonorrhœa 16 per cent. developed arthritis.

Symptoms.—A study of these admits a classification as made by the late R. P. Howard, of Montreal, into seven subdivisions:

1. The purely *arthralgic* form, *i. e.*, cases characterized by pain, but not much other evidence of local inflammation. Fever is also absent, although the condition is apt to be polyarthritic, wandering from joint to joint.

2. *Rheumatoid gonorrhœal arthritis*, resembling more than all other forms acute inflammatory rheumatism. In this division fever is added to the local symptoms of rheumatism, and polyarthritic involvement is also common. The fever, however, is less severe than would be expected from the severity of the other symptoms. The maximum temperature may be 102° F. (39° C.), more frequently it is less than this.

3. *Acute gonorrhœal monarthritis*, in which one joint only is involved, with severe pain and swelling and moderate fever. It is the knee-joint that is most commonly attacked in this monarthritic variety. Next in order follow the ankle, shoulder, elbow, and wrist; any one of these is liable to be the seat of the trouble. Suppuration is rare.

4. *Chronic gonorrhœal arthritis*, without or with effusion (chronic hydro-arthritis). Suppuration, though rare, does take place and pus is found in the joint cavity. In these cases, too, there is generally slight elevation of temperature.

5. The *periarthritic* variety, including cases in which the periarthritic tissues are involved, including the capsule, ligaments, tendons, and adjacent fibrous structures. The periosteum is included among these, but the joint cavity itself is not affected.

6. A variety which invades *fibrous tissue not connected with joints*, as the plantar fascia, the sclerotic coat of the eye and iris, the pericardium and endocardium.

7. The *septicemic form*, where, in addition to the arthritis, there is general sepsis and endocarditis. In this event there are the usual signs of blood invasion, high fever with or without chills, and sweats.

Complications.—Isolated and even multiple cases of endocarditis associated with gonorrhœal rheumatism have been reported by German and French physicians during the past thirty-eight years. Comparatively

recently the studies of Gluzinski (1888) and R. L. MacDonnell* have settled the question in favor of a causal relation, the latter having found endocarditis present in 4 out of 27 cases of gonorrhœal arthritis, while Gluzinski collected 31 cases. They may reasonably be attributed to the action of the micro-organisms on the valves. Malignant endocarditis may be thus caused.

Pericarditis and pleurisy similarly caused may complicate the disease, as may also iritis and sclerotitis.

Treatment.—This is not always satisfactory. The salicylates are sometimes distinctly efficient, especially in the more acute forms. Iodid of potassium is perhaps the drug most commonly found useful, and its effect is increased when combined with the bichlorid of mercury. It must, however, be associated with rest and local treatment. The former is sometimes better accomplished by the use of splints, the latter by blisters or iodin. General roborant treatment by tonics and good food may also be necessary. The ammoniated tincture of guaiac may also be used as in chronic rheumatism.

Dr. James C. Wilson † has reported satisfactory results from large doses of the syrup of iodid of iron, as much as a fluid dram (4 c. c.) four times a day, beginning with smaller doses.

PNEUMONIA.

CROUPOUS PNEUMONIA.

SYNONYMS.—*Pneumonitis; Lobar Pneumonia; Fibrinous Pneumonia; Genuine Pneumonia.*

Definition.—An acute infectious inflammatory disease of the lungs, characterized by high fever, and usually terminating by crisis in from five to nine days. A bacterium especially prone to occur in pairs or chains, known as the *diplococcus pneumoniae*, *diplococcus lanceolatus*, or *micrococcus pneumoniae crouposa* (Sternberg), is found in 75 per cent. of all cases of lobar pneumonia and is commonly regarded as its cause.

Varieties.—The term *lobar pneumonia* is used for this form because it generally involves at least a single lobe or the greater portion of one. The term *pneumonia of the apex* is used where one or both apices of the lung are involved. A rare form of pneumonia is *double pneumonia* in which both lungs are involved, though not necessarily the whole of each lung. A *massive pneumonia* is an inflammation not only of the air-vesicles, but of the bronchi of a lobe or even of the whole lung. A *creeping* or migratory pneumonia affects successively different lobes of the lung. *Epidemic pneumonia* involves large numbers or communities. The term *larval pneumonia* is applied to a form of the disease in which but a partial development of symptoms occurs, such as a moderate chill, slight fever, and imperfect local signs. It occurs more particularly in connection with epidemics or with pneumonias in crowded places, as ships, camps, and garrisons.

* "Gonorrhœal Rheumatism." "Am. Jour. of the Med. Sci.," January, 1861.

† "Iodid of Iron in the Treatment of Certain Forms of Infective Arthritis," "Jacobi Festschrift," 1900, p. 350.

Historical.—Evidently what we now know as *croupous pneumonia* was known to the earliest medical writers, including Hippocrates (B. C. 400–357), who, with others, described it with considerable accuracy as *peri-pneumonia*, or *pleuritis*. Hippocrates said of it that it was a “disease quickly fatal and characterized by sputa of various colors.” Lesions and symptoms corresponding to it were described by Thucydides in his description of “The Plague of Athens,” B. C. 430. Sydenham (1679), Valsalva (1666–1723), Morgagni (1761), Boerhaave (1668–1738), all gave good descriptions, but failed to separate it from pleurisy. Laennec (1819) was the first to sharply separate the two diseases, and made the classification into the three well-known stages, which hold to-day as then—congestion, hepatization, and resolution or suppuration. The nature of the exudate was first accurately described from the macroscopic standpoint by Rokitansky in 1841. Ziemssen (1857–58) furnished valuable data on the geographical distribution of pneumonia. Grisolle (1864) especially collected valuable statistics relating to climate, development, and comparative frequency among different races.

Etiology.—The infectious nature of pneumonia was first advocated by Jürgensen in 1872. The presence of a special organism in the secretions of hepatized lung, in the fibrinous exudate into the alveoli, and in the sputum was demonstrated by Friedländer in 1883, and again by Fränkel in 1886. The organism discovered by Friedländer was called by him *pneumococcus*, while Fränkel applied to his the term *diplococcus*. The two organisms are not identical.

The pneumococcus of Friedländer is a short, oval bacillus, always enclosed in a capsule, which usually contains one coccus only, rarely two or more. It is non-motile and anaërobic—that is, grows without oxygen. When treated with the aqueous staining solutions (as carbol-fuchsin), the bacillus is stained, the capsule being only slightly colored. It cannot be stained by Gram’s method. The cocci do not liquefy gelatin, and stick-cultures develop into a nail-like growth with a thick head. The cocci flourish in agar and on the potato. They are found in 5 to 2 per cent. of cases of pneumonia.*

The *diplococcus* of Fränkel, to which the name Weichselbaum has also been added, is the true pneumococcus. It occurs in pairs, sometimes in rows or beads. It is also pointed at one end, whence the term *bacillus lanceolatus*, “lancet-shaped.” Like the pneumobacillus of Friedländer it is encapsulated when in the body, but not when cultivated out of the body. It differs from Friedländer’s bacillus in that when stained by the carbol fuchsin solution the coccus is intensely red, while the capsule assumes a light reddish tint. Further, it can also be stained by Gram’s method, while the pneumococcus of Friedländer cannot. It thrives on agar and in bouillon, but not on gelatin. It is probably the same organism as that found by Sternberg in rabbits inoculated with his own saliva in 1880, but not announced until April, 1881. Pasteur had also recognized the same organism in the saliva and published several notes on the same subject, January to March, 1881. The coccus occurs, according to Netter, in 20 per cent. of all persons. Fränkel, Talamon, and especially Weichselbaum showed the relations of this organism to pneumonia. The latter found it in 92 per cent. of cases of croupous pneumonia. William H. Welch found it in every one of ten cases of croupous pneumonia studied at the Johns Hopkins Hospital at Baltimore. It has been found in the blood, in the spleen and kidney, in endocardial vegetations, and in the pus of cerebrospinal meningitis where there was no pneumonia, as well as in the saliva of healthy persons and in the dust on the floors of houses. Its route of entrance is probably the respiratory passages, since it has been found in the nose, larynx, and Eustachian tube, and is said

* The opinion at present appears to be that the bacillus of Friedländer is a feeble pathogenic organism, a harmless saprophyte, as a rule, but able, at times, to produce inflammatory effects.

to persist for months and even years in the saliva of healthy persons who have had pneumonia. On the other hand, it is a very perishable organism, maintaining its virulence outside of the body for four or five days only.

That the pneumococcus of Fränkel is not the only organism capable of producing pneumonia is, however, evident from the experiments of Fränkel himself, of Weichselbaum, and of Pansini and Neumann. It may be accompanied by pus organisms and others which may be responsible for complications and modifications of the ordinary pneumonic process. Streptococcus pneumonia has come to be recognized as a variety of pneumonia having a more or less distinct clinical picture that will be again referred to.

Nature of Pneumonia.—Thus *caused*, pneumonia may be regarded from two standpoints. First, it may be a general disease with a local expression in the lungs, analogous to the inflammation of Peyer's patches in typhoid fever; or it may be a local disease, which, like diphtheria, infects the general economy and produces the constitutional symptoms characteristic of it. As in the case of typhoid fever, there were facts which pointed to the infectious nature of pneumonia long before the discovery of any organism that could be regarded as its specific cause. The occurrence of pneumonia in epidemic form was recognized by Laennec and Grisolle, and since their day innumerable epidemics have been described: house epidemics, including those in which a number of individuals, from three to ten or more, have been attacked under the same roof, and general epidemics, invading institutions, ships, and garrisons, in which large numbers of persons are congregated. Out of a ship's crew of 815, 410 were attacked in rapid succession, and out of 720 attacked, 298 perished.

While the state of knowledge at the present day seems to demand that we consider croupous pneumonia as an infectious disease due to the action of a specific organism, we cannot ignore the operation of causes, such as dampness and cold, which until recently have seemed sufficient to account for a large number of cases. Thus an overworked man is exposed to cold for a long time, and becomes thoroughly *chilled*. A few hours later he is seized with a rigor, and twenty-four hours afterward the physical signs of a pneumonia have developed. The lowered vitality consequent on the exposure in each case must be regarded as a predisposing cause, preparing the system for the operation of the ever-present organism as the exciting cause. The operation of cold is further seen in the influence of the seasons, pneumonia being much commoner in the winter months. Other predisposing causes are: a previous attack, fatigue of mind or body, and debilitating conditions of all kinds, such as previous or present illness, especially a chronic complaint, such as Bright's disease. A patient of my own had four attacks and succumbed to a fifth. Heredity is also said to be a factor, and injuries of the chest have long been regarded as predisposing causes.

Morbid Anatomy.—The lung in croupous pneumonia exhibits three distinct stages:

1. Congestion or engorgement.
2. Red hepatization.
3. Gray hepatization.

Pneumonia seeks, by preference, the lower lobes of the lungs, and the right lung more than the left. Pneumonia of the apex, however, not infrequently occurs, more often in children than in adults.

The Stage of Congestion.—In this stage the lung is engorged with blood, yet permeable to air. The capillaries surrounding the air-vesicles are

turgid and intrude upon the lumina of the air-vesicles. There is a small amount of transudate, in which may be found a few exfoliated alveolar cells and red blood-discs. The part of the lung invaded is redder than normal and heavier, but not nearly so heavy as in the next stage. On section, blood transudes from the cut vessels and bathes the surface.

The Stage of Red Hepatization.—In this the lung is dark red in color, hard, and very much heavier than in health—as much as three and four times the normal weight. A piece dropped in water rapidly falls to the bottom. The lung pits on pressure, and in consequence the marks of the ribs are often seen on it after removal. On section the aptness of the name red hepatization is at once apparent. The surface is darker in color than in the first stage, and it has the appearance of a section of liver. On passing the finger over it, innumerable little hard spots like grains of sand are felt. These are air-vesicles filled with the croupous exudate. Corresponding to this, a granular appearance is recognized by the eye, the distended air-vesicles appearing as glistening points. By scraping, little plugs of fibrin and cellular detritus mixed with serum can be removed. The lung, though thus hard, is nevertheless friable, and may be broken up by the fingers.

Histologically, the air-vesicles are found to contain a delicate reticulum, the meshes of which are filled with red blood-discs, and with alveolar cells in different stages of degeneration, including numerous granular fatty cells or compound granular cells. The vesicular walls are found infiltrated with lymphoid cells, which extend even into the interlobular tissue beyond them. Plugs of fibrin may sometimes be traced into the smaller bronchi from the air-vesicles.

The diplococcus of Fränkel and pneumococcus of Friedländer may be demonstrated in cover-glass preparations made from the exudate. They may be associated with the streptococcus and staphylococcus.

The Stage of Gray Hepatization.—This is also well named, the cut lung exhibiting a grayish-white coloration. It is still dense and heavy, but much moister and softer, and even more friable. The granulations are, however, less distinct, and on microscopic examination the alveoli are found filled with white blood-corpuscles, while the red corpuscles and fibrin filaments have disappeared. Sometimes all three stages are seen alongside of one another.

A stage beyond gray hepatization is sometimes spoken of as a *stage of yellow hepatization*. In this stage the lung has assumed a more yellowish appearance, it is much softer, almost liquid in consistence, and more like pus. On minute examination the air-vesicles are filled with pus-cells, the points of greatest softness constituting small abscesses as large as a pin's head and larger. The stage of gray hepatization is the stage of beginning resolution, while that of yellow hepatization represents the same stage in which the proportion of leukocytes undergoing fatty degeneration is larger.

If recovery takes place the contents of the air-vesicles liquefy, the product being partly expectorated, but probably mostly absorbed.

The *pleura adjacent* to the inflamed lung is almost always inflamed, the most distinctive sign of this being a plastic deposit. There may also be thickening and some serous effusion.

After death from pneumonia, the *heart* is found in a typical pathological condition. The left cavities are generally found empty or nearly so, while the right are distended with firm coagula, which often extend into the branches of the pulmonary artery. The *spleen* is often enlarged. The cells

lining the *renal tubes* are often found in a state of cloudy swelling; rarely there is nephritis.

Symptoms.—Perhaps no other disease except malarial fever is so invariably ushered in by a *chill* as is croupous pneumonia, and often a chill of great severity. It may come on at night, waking the patient out of a deep sleep. It may or may not be preceded by a day or two of *prodromal discomfort*, with *headache*, which may be very severe. Almost immediately there succeeds a high fever, in which the temperature rises rapidly to from 103° to 105° F. (39.4° to 40.5° C.). A significant *flush on each cheek* is characteristic, occasionally more marked on the affected side. The pulse is full and strong, resisting pressure, rate 100 to 120. There is *thirst*, and *the urine is scanty and high colored*, sometimes albuminous. Equally promptly ensues a *pain in the side*, which may be dull, but is often also sharp and severe, caused in the latter instance by involvement of the pleura. The *respirations* rise rapidly in frequency, and there is *cough*, at first dry and hard. It is often restrained on account of the pain it occasions. Soon there is a small amount of *mucous expectoration* from the coincident bronchitis, but usually in twenty-four to forty-eight hours after the chill the sputum exhibits distinctive characteristics. It is tenacious, light red in hue,—“rusty,”—and is ejected from the mouth with difficulty. At other times it is much thinner and darker, and has received the name “prune-juice” expectoration. The amount of blood and the degree of coloration vary greatly. The *respirations* are exceedingly rapid—50, 60, and even more in the minute. I have known them to be 82, and in a child they may reach 100. The appearance of a patient at this stage is very striking. The face is flushed, the eye is brilliant, the breath is rapid, the *alæ nasi* move with each breath, while a frequent short cough, held back until irresistible, increases at times the already anxious expression of the patient.

This state of affairs continues unchanged for from five to nine days, when, if recovery takes place, a sudden drop in the temperature occurs, accompanied often by free perspiration, while a state of comparative comfort succeeds to one of great distress, to be further followed oftentimes by a long and refreshing sleep. This is known as the *crisis*. It may be preceded by a fall of temperature a day or two earlier, which is again followed by a rise, whence such fall is called the pseudo-crisis. The accompanying temperature chart (Fig. 20), from a case seen in consultation with Alfred Stengel, illustrates the actual crisis. The fall in crisis is sometimes as much as 7° F. (12.6° C.) in twenty-four hours, and the minimum is quite often slightly subnormal, whence it rises rapidly to the normal.

From this point onward convalescence is rapid, and in four or five days more the patient is seemingly well, the temperature and pulse-rate normal, the breathing natural. A muscular weakness and vulnerability, however, remain, which demand care for a time longer.

The duration of the stages may be roughly stated as twenty-four hours for the first, five to eight days for the second, and a few days to several weeks for the third.

Physical Signs.—The physical signs of a typical pneumonia are very distinctive.

The *first*, or *stage of congestion*, in which the air-vesicles are still open, is of short duration, terminating within the first twenty-four hours, and may therefore be overlooked. *Inspection* shows the face flushed, increased frequency of respiration, with restricted movement upon the affected side and

increased extent of motion on the sound side. The patient lies by preference on the affected side because of the greater comfort it gives him. This posture not only diminishes the pain by hindering the motion of the affected side, but also lessens the dyspnea by permitting unrestrained expansion of the side that is doing the work.

Palpation at first may even find vocal fremitus diminished on account of the relaxation of the air-vesicles, but it becomes decidedly increased as the latter fill up. The skin is hot and the pulse is frequent, full, and strong, as a rule. *Percussion* obtains but slight, if any, impairment of resonance. In fact, tympany, or the vesiculo-tympany of Flint,—Skoda's resonance,—may be present in this stage as a result of the relaxation of the partially filled air-vesicles, giving resonance by immediate relaxation. In the latter part of the first stage there is, however, impairment of resonance.

Auscultation in the very earliest stage may find the vesicular murmur feeble, but very soon is heard the distinctive physical sign of pneumonia, the *crepitant râle* at the end of inspiration. If there be coincident pleurisy,—pleuropneumonia,—the closely simulating friction sound may be added. Under such circumstances it may be difficult to distinguish these two physical signs. Over the normal part of the lung there is exaggerated vesicular breathing.

Fig. 20.—Showing Crisis in Pneumonia.

But all these physical signs, even if carefully sought for, may be wanting if the pneumonia be central and deep-seated, as is not infrequently the case. They appear as the surface is approached, or they may not be recognized at all if the disease remains central.

The *second stage*, or *stage of red hepatization* or solidification, lasting four or five days, furnishes unmistakable signs. All the signs pneumonia

reveals to *inspection* in the first stage are intensified in the second, and the breathing is markedly abdominal. To *palpation*, vocal fremitus is now intense, the skin is hot and dry, and the pulse continues frequent. Mensuration almost always and even inspection may recognize an enlargement of the involved side, the former to the extent of 0.5 to 2.5 cm.

Percussion gives absolute flatness over the solidified area, with high pitch and short duration, except in those very rare instances where the extreme consolidation throws the column of air in the trachea and bronchi into vibration, producing tympany. This explanation is perhaps the only one when tympany occurs in the upper lobe. In a lower lobe, tympany may result in the same way, from the proximity of an air-distended stomach. Over the adjacent normal areas, also, resonance is exaggerated, not so much, perhaps, in consequence of supplemental function, as from relaxation of the adjacent air-vesicles—Skoda's resonance by mediate relaxation. Even cracked-pot sound may be produced by percussion over the solidified lung as a result of the sudden expulsion of air from a large bronchus leading to the solidified area.

Auscultation discerns high-pitched bronchial breathing over the solidified lung. Indeed, these are the circumstances that give the typical bronchial or tubal breathing. The air-vesicles are obliterated, and the resulting excellent conducting medium brings the tracheo-bronchial blowing to the ear. In very rare instances, when the larger bronchi are filled with exudate, there may be no bronchial breathing. The ausculted voice gives us typical bronchophony and occasionally even pectoriloquy, as well as whispering bronchophony and pectoriloquy. The heart-sounds are also heard with great distinctness over the consolidated lung, owing to the improved conduction, while the sounds of a concurrent bronchitis are similarly intensified. A lingering crepitant râle may also be heard.

The *third stage*, or *stage of gray hepatization* or resolution, occupies six to ten days. It repeats largely, to inspection, palpation, and auscultation, the phenomena of the first. Resonance continues impaired for some time. The normal manner of breathing gradually returns, the temperature of the skin is notably less, the crepitant râle returns, technically known as the "crepitans redux," and is finally replaced by the normal vesicular breathing sound, by which time the dullness has disappeared.

Croupous pneumonia may rarely terminate in *abscess* or *gangrene*; in either event the signs of the second stage continue and the temperature does not fall—in a word, the crisis does not occur. The signs of a cavity, which might naturally be expected, are rarely present, and it is rather by the general symptoms, viz., the failure to recover, the continued high temperature, the expectoration of pus, and, in the case of gangrene, the intensely disagreeable odor, that we are informed of the issue. These issues probably represent on a large scale what takes place in every instance in minute areas in the third stage of all pneumonias which terminate favorably. The occasional termination in tubercular phthisis exhibits a similar arrest of the resolving process in the second stage, and the phenomena of catarrhal or fibroid phthisis supervene.

The obscuring effect of a thickened pleura upon all these signs is to be remembered, and too much stress cannot be laid upon the fact that we may have a central deep-seated pneumonia that may give no physical signs; also that in old persons the physical signs of a pneumonia are very apt to be delayed from one to three days.

Careful differential percussion and palpation may recognize a moderate enlargement of the *spleen*.

The *heart* should be carefully watched in pneumonia. The sounds, at first loud and clear, become less so as the disease progresses and the lungs become engorged. The pulmonic second sound is particularly sharp as long as the heart is strong, and its failure is an unfavorable sign, as it means that the right ventricle is failing in power and may be yielding to distention.

Modifications in Symptoms and Special Symptoms.—The foregoing is the course of a typical case of pneumonia, perhaps of three-fourths of all cases, and the symptoms mentioned suffice for a diagnosis. All of them are, however, subject to modifications.

Thus, the *chill* may be absent or imperfectly developed, in which case all the symptoms arise more gradually. The *temperature*, especially in old persons and drunkards, may not be nearly so high; in children it may be higher. The same is true of the *respirations*, which may be increased to 100 to the minute in children. *Pain* is especially absent in old persons, *cough* and *expectoration* also, so that a careful physical examination of the lungs should be made in all ailments in the old and in drunkards also, as it not infrequently happens that pneumonia is overlooked in them. The *pulse* is often feeble and rapid instead of full and strong. Nay, more, even the *physical signs may be absent in the old*, and they are especially apt to be delayed in their development. It is unsafe to say of an old person at the first visit, after a negative physical examination, that he has not pneumonia, for the physical signs may not make their appearance until the second or third day and even later. It would seem, too, that central pneumonia is more common in the old than in the young, while even an afebrile pneumonia is a possibility in the old. Even in younger persons the appearance of physical signs is sometimes delayed three or four days.

The *expectoration* varies a good deal when present, especially as to the quantity of blood. Sometimes it is bright red and quite liquid, almost like a hemorrhage. More frequently it is viscid and glutinous, simply stained with blood. The term "prune-juice expectoration" has long been associated with pneumonia, and sometimes, when it is thin and dark-hued, the comparison is an apt one. Under the microscope the sputum is found to contain blood-discs, leukocytes, and alveolar epithelium in various stages of degeneration, including numerous compound granule-cells, also ciliated epithelium. *Fibrinous bronchial coagula*, sometimes large enough to be seen by the naked eye, are also met with in the expectoration, and, after suitable staining, diplococci. Should gangrene supervene, the expectoration becomes very fetid.

The *urine* is especially characterized by a reduced amount of chlorids, which are often absent until the crisis is passed, when they reappear. It is supposed that during this period they are transferred to the exudate in the lungs. A trace of albumin is often present and it presents the other features of febrile urine.

There is sometimes *marked jaundice*. It may even be the first symptom. It may be a catarrhal or a hematogenous jaundice. The cases attended by it are rather more serious. Various explanations have been suggested. According to one, it is due to a catarrh of the bile-ducts; according to another, it is due to a reabsorption of the hemoglobin derived from disintegration of the red blood-disc of the exudate in the air-vesicles; and according to still another, it is due to a congestion of the liver. All these

views are speculative. Recently G. Mante* ascribes it to a hemolytic action of the *diplococcus lancetolatus*. His conclusions are based upon experiments going to prove that such hemolytic action takes place.

The blood exhibits usually a *leukocytosis*, the number of corpuscles being increased from 6000 per cubic millimeter to 19,000, or more. As many as 68,000 have been found. The increase is almost always in the polymorphonuclear cells. The proportion of fibrin is also increased from 4 to 10 parts in 1000. This increase of fibrin shows itself also on the microscopic slide in the shape of filaments of fibrin. According to Hayem, the blood-plaques are increased.

Herpes is very common on the lip—present, it is said, in from 12 to 40 per cent. of all cases. It may occur elsewhere, as on the nose and genitals.

Phlegmasia alba dolens, or milk-leg, is a rare sequel. J. M. Da Costa † collected nine cases, of which three were his own. The complication occurs late and has been more frequent in the left leg.

When typhoid fever coexists with croupous pneumonia the tongue is coated, and becomes dry and leathery. Constipation is usual, but occasionally there is diarrhea, especially in epidemics. Except in typhoid cases *delirium* is not common, but may be very active in the young. In old persons it may be low and muttering. In drunkards, in whom the disease is common and very grave, especially after a debauch, the delirium may be taken for *mania a potu*, or the two may coexist. Such a patient may rise from his bed and wander out into the city or to another hospital that he prefers, having just intelligence and strength enough to accomplish this purpose, and will die after its attainment.

Streptococcus pneumonia has been mentioned, with the statement that it presents some clinical features different from those of the ordinary croupous pneumonia, at least at times recognizable. I must say, however, that I am not myself confident of being able to recognize such pneumonia by these symptoms, since many of them are the same as those heretofore regarded as peculiar to bronchopneumonia as ordinarily caused. In the first place, it is held that the serious form of pneumonia, which often complicates influenza, is thought to be a streptococcus pneumonia. Such pneumonias, like bronchopneumonia, commonly begin obscurely, are atypical, while the local signs are slow to develop. The rusty expectoration is delayed; in like manner the crisis, which may be substituted by lysis; or death supervenes instead of crisis. The physical signs also rather resemble those of bronchopneumonia, while it is said ‡ that the disease is more frequently found in the upper lobe, not at its apex, but in its lower part between the inferior angle of the scapula and the axilla. It may also be irregularly migratory. The sputum may be mucopurulent at the outset, and is always less conspicuously red or rusty. Like bronchopneumonia, it is also insidious in its onset, the fever is irregular, and there is often chilliness or actual rigor with sweats; in a word, septic symptoms are prominent.

Termination.—When the pneumonia terminates favorably, promptly after the crisis is passed, it is said to terminate by:

1. *Resolution*, by which is meant that the inflammatory product liquefies, is absorbed or expectorated, and the lung resumes its natural state and normal physical features. The time at which these events are thoroughly

* "Centralblatt für Bakteriologie," etc., December 10, 1896, p. 849.

† "Philadelphia Med. Jour.," vol. ii., 1808, p. 510.

‡ G. Baumgarten, "Variations in the Clinical Course of Croupous Pneumonia," "International Clinics," vol. ii. Sixth Series, 1896.

established varies greatly, and if there happens to have been associated pleurisy, with resulting thickened membrane, impairment of resonance may last a long while. On the other hand, it may terminate spontaneously even earlier than the periods named for the crisis. In such event the pneumonia is said to abort. This promptly favorable termination does not always take place. Resolution may be unduly delayed and yet ultimately take place. Such cases naturally occasion anxiety, for resolution may not take place at all, in which event one of five unfavorable terminations may occur. These are:

- (a) Death from cardiac failure.
- (b) Abscess.
- (c) Gangrene of the lung.
- (d) Interstitial or fibroid pneumonia.
- (e) Tubercular phthisis.

2. *Abscess of the lung* is a termination of pneumonia in about 4 per cent. of fatal cases. Flint, Sr., found it in 4 out of 133 cases recorded. When this occurs, the interstitial tissue of the lungs becomes infiltrated with pus cells, small foci of leukocytes aggregate to form larger, until a large abscess results, which may occupy a whole lobe or even a whole lung. In such cases the fever continues high, there is expectoration of pus containing elastic tissue of the lung, and the physical signs of a cavity may rarely be present. It is not impossible, however, for such a process to be arrested by a reactive inflammation, by which a tough protective layer of embryonic tissue is formed about the abscess.

3. *Gangrene of the lung* occurs in about 3 per cent. of fatal cases. It is especially prone to occur where the pulmonary vessels become so engorged that the circulation is arrested, and where, as a consequence, the hemorrhagic element is conspicuous. Bronchiectatic cavities in an inflamed lobe that are swarming with putrefactive bacteria are an important predisposing cause. It is recognized by the sickening fetor, which pervades a whole ward, and which, once met, is never forgotten. The expectoration is thin and similarly fetid, and contains large quantities of elastic tissue from the lung. The lung is converted into a gray-green, fetid pulp, in which cavities with ragged walls arise, from disintegration and expectoration of lung tissue. Gangrenous portions may be surrounded by a zone of true inflammation, contrasting by its red color with the gray of the gangrene. Such sloughs have been successfully excavated by surgical treatment.

4. In *fibroid induration or cirrhosis*, which is occasionally met with, there is also invasion of interstitial lung tissue, but instead of being infiltrated by such an excess of leukocytes as to produce pus, only as many wander out as can undergo organization and conversion into permanent tissue. Sometimes this results from the lung failing to expand after resolution and absorption of the exudate, the walls of the unexpanded alveoli collapsing and uniting. In other cases there is partial absorption of the exudate, repeated infiltration takes place into the alveolar septa, and organization takes place in both. The fibrinous plugs may also be transformed into connective tissue. Three successive stages may be present. In the first the cirrhotic patches are gray, grayish-red, or grayish-yellow, and a small amount of turbid exudate can be here and there squeezed out of them. In the second stage, where the formation of the fibrous tissue in the alveoli or their walls has set in, the lung is dense, firm, airless, and fleshy, whence the term *carnification*. In the third stage the fibroid transformation is com-

plete; the tissue is tough and slate-gray in color. Such induration is generally in bands and patches that merge gradually into the normal vesicular structure.

5. *Tubercular phthisis* is another termination of pneumonia. It results from infection by implantation of the tubercle bacillus. Pneumonia of the apex terminates thus most frequently.

Complications.—The most frequent complication is *pleurisy*. It is probably always present to a certain extent, except in the central forms. It manifests itself in the first stage more by the characteristic severe cutting pain than by physical signs, as the friction sound characteristic of that stage is commonly obscured by the physical signs of the pneumonia. Should the stage of effusion be reached, the physical signs of the pneumonia subside. In severe cases a pleurisy may surround the entire lung and bind it to the chest-wall. A pneumonia on one side and a pleurisy on the other is a possibility. That very interesting pathological state known as pleurogenic pneumonia is sometimes seen in the human being as a form of tubercular pleurisy. In it the lung becomes partitioned off by an interstitial framework starting from the pleura. It has its typical anatomical product in the pleuropneumonia of cattle. The extension takes place chiefly by way of the lymphatics.

Endocarditis is a comparatively frequent complication. William Osler especially called attention to this fact in his Gulstonian lectures for 1885. He ascertained that of 209 cases of malignant endocarditis 54, or over 25 per cent., occurred as complications of pneumonia. It is more prone to attack persons with old valvular disease, and to involve the left heart. There is good reason to believe that the specific lancet-shaped bacillus is responsible for this form of valvulitis as a complication of pneumonia. The endocarditis constantly escapes detection, since physical signs are sometimes absent, at others deceptive, but it may be suspected:

1. When the fever is protracted and irregular.
2. When signs of a septic condition arise, such as irregular temperature with chills and sweats.
3. When embolic pneumonia develops.
4. When a loud, rough murmur, especially a diastolic aortic murmur, develops in the course of the disease.

Meningitis is another complication to which Osler has called especial attention, finding it in 8 per cent. of fatal cases. It usually comes on at the height of the fever, and may be confounded with delirium. It is often associated with endocarditis, and it *may be accompanied by cerebral embolism, producing hemiplegia*. *Neuritis* is a possible complication.

Parotitis occasionally occurs, commonly in association with endocarditis. In children middle-ear disease is not an infrequent complication.

Diagnosis.—The diagnosis of a case of typical pneumonia is easy. The chill, the rapidly developed fever, and the physical signs are, as a rule, easily recognized. It is to be remembered, however, that the physical signs may be delayed or not appear at all in the central varieties.

Pleurisy is the disease from which pneumonia has most frequently to be distinguished. The resemblance between the friction sound and the crepitant râle is often very close, while there is impaired resonance to percussion in both. Most valuable in diagnosis is vocal tactile fremitus, which is invariably increased in pneumonia and as invariably diminished in pleurisy of any variety. In the not very rare instances of pleurisy with effusion

attended by bronchial breathing the same sign is pathognomonic, tactile fremitus being diminished, whereas it is increased in pneumonia. Commonly, too, in this stage of pleurisy we have a change in the line of dullness as the patient changes position, though this is not invariable. The exploring needle, if needed, may also help settle that question.

Frequent examination of the lungs should be made in alcoholism, in chronic valvular disease of the heart, in diabetes, and in Bright's disease, since all these affections are prone to become complicated with insidious forms of pneumonia.

Typhoid fever and pneumonia are sometimes confounded. The former is apt to become associated with hypostatic congestion of the lungs, and pneumonia with a typhoid state. The hypostasis, however, occurs late in typhoid fever; the dullness in pneumonia sets in early. A more excusable error is made in the case of *acute tuberculopneumonic phthisis*, which may begin with a chill, while the resemblance is otherwise very close, especially in physical signs. Microscopic examination of the sputum should recognize the bacilli of either disease. This should always be made where an apparent pneumonia is prolonged beyond two weeks without a crisis. In pneumonic phthisis the appearance of bacilli is generally late.

Prognosis.—Pneumonia is a treacherous and uncertain disease at any age. Young, robust men of twenty-five, taken mildly ill with every reasonable expectation of recovery, sometimes die suddenly and unexpectedly. On the other hand, while in the old and intemperate it is especially dangerous, old men and women over seventy often recover completely. The intemperate are less fortunate, yet even among them some surprising recoveries are observed. The mortality ranges from 20 to 40 per cent., or about one in four or five die. It is the most fatal of the acute infections of adults in temperate climates. Children recover often, even when desperately ill. The disease seems to be more fatal in cities than in the country, and is certainly so during epidemics, or in ships or other crowded places.

The seriousness of an attack varies more or less with the extent of lung involved, pneumonia of a whole lung being more dangerous than that of a part, double pneumonia more than that affecting one lung, while massive pneumonias are always fatal. Meningitis is invariably fatal, but its presence must not be inferred from every violent delirium. Endocarditis is almost as fatal. Death is usually by heart failure, the right ventricle becoming stretched by the accumulated blood, and the valves and columnæ carneæ embarrassed by fibrinous coagula, which may extend from auricle to ventricle and even into the branches of the pulmonary artery.

The conclusion is apparently unjustified by a study of statistics,* but it does seem to me that pneumonia is a more fatal disease now than when I began practice thirty-five years ago.

Treatment.—A fundamental principle which experience has established is that no single plan of treatment dare be recommended for pneumonia, but that each case is a law unto itself. This is more or less true of all diseases, but it is especially so of pneumonia. Undoubtedly cases occur that are best treated by general blood-letting, while many more do not require it, and a few may be harmed by it. Pneumonia may be a general disease and not a local one, and the lung involvement may be secondary; at the same time the patient often dies from the direct effect of such local involvement. It is the

* For an excellent analytical examination of the statistics of pneumonia the reader is referred to a paper in the "Medical News," July 27, 1889, by Drs. Townsend and Coolidge, Jr., based on a study of the cases treated in the Massachusetts General Hospital.

obstruction to the movement of the blood through the lungs which strains and wears out the right heart. The blood-letting, if it is done early, lessens this congestion, and thus relieves the right heart. More frequently perhaps at the present day the patient dies of the effect of the toxin on the heart and nervous system.

What are the indications for blood-letting? There are two periods in a pneumonia where blood-letting may be of advantage: First, in the first stage and early part of the second stage, and, second, where there is engorgement of the right heart. The indications in the first period include (1) great dyspnea; (2) full, bounding pulse; and (3) sharp, pleuritic pain. The relief to all of these symptoms is often magical. The amount of blood taken at such time should not be less than 16 ounces (480 c. c.), but not the quantity of blood so much as the relief to the symptoms should be the sign to stop the bleeding. The same results may be accomplished by wet-cups, provided a sufficient amount of blood be taken, and cupping has the appearance of being less formidable, although it is actually more painful and disturbing to the patient. After the removal of the cups a poultice or warm cotton jacket is comforting. If doubt is entertained as to the propriety of either of these two methods of bleeding, the affected lung should be covered with dry-cups, and after the removal of these the hot poultice or hot jacket applied. Even by this method the relief to the pain and dyspnea is often very great, but it is more likely to be temporary. Dry-cupping may, however, be repeated daily, if it affords relief. While there are cases in which the adynamia is so great as to make blood-letting in any form of doubtful propriety, there can be no possible objection to the dry-cups. Bleeding, besides relieving the symptoms referred to, hastens the crisis and shortens the disease.

The indications in the second period are rapid breathing with cyanosis and laboring pulse. At this stage the removal of 10 to 16 ounces of blood is often of signal service, and I believe I have seen life saved by such a blood-letting.

These measures may also relieve the *cough*, but usually something additional is required. Until expectoration sets in, *opium* is pre-eminently the remedy, and no preparation is so good as *morphin* in doses of from 1-16 to 1-12 grain (0.004 to 0.005 gm.) for adults every two hours in 1-2 ounce (15 c. c.) of the solution of citrate of potassium flavored with lemon or other syrup. *Dover's powder* in full doses sometimes acts favorably. It is best given in pill form. Expectorants are rarely needed at the outset, but *ammonium chlorid* in doses of 5 to 10 grains (0.32 to 0.65 gm.) in brown mixture, also combined with morphin if necessary, will meet the indications. If a still more stimulating expectorant is required, the *carbonate of ammonium* may be used in doses of 5 to 10 grains (0.32 to 0.65 gm.) frequently repeated. It is an important fact, often overlooked in prescribing diffusible stimulants, that to get a desired effect they should be frequently repeated, and it is better to give small doses often than large doses at longer intervals.

Pneumonia calls very soon, sometimes from the very outset, for *alcoholic stimulants*, which act not only on the heart, but also as antipyretics. Half an ounce or even an ounce (15 to 30 c. c.) hourly, in cases of extreme adynamia, may be necessary. The index of sufficiency or the reverse is the state of the pulse and heart. Whisky or brandy, as selected, should be given in milk, which is the most suitable nourishment. From 4 to 8 ounces (120

to 140 c. c.) of milk every two hours, containing the proper dose of stimulant, may be given.

Strychnin is an invaluable heart tonic in pneumonia, and may be given in doses of 1-30 grain (0.002 gm.) or more, every four to six hours, combined with 8 to 20 grains (0.52 to 1.30 gm.) of *quinin* in the twenty-four hours, as may be required.

Digitalis is a remedy much used in pneumonia, and it is a useful drug, but it is not always judiciously ordered. To whip up a flagging heart to increased effort to drive blood through a lung almost as solid as a stone is like whipping up a jaded horse to an effort beyond his strength, and is about as ineffectual. On the other hand, such a stimulus may tide over an obstacle which is not insurmountable, but which might remain in the way unless removed. On the whole, I prefer to give *digitalis* in moderately full doses, 5 to 10 minims (0.3 to 0.6 c. c.), as an adjuvant to alcohol rather than in very large doses. Occasionally in sudden adynamia very large doses, say 1 dram (3.7 c. c.), hypodermically, may turn the tide toward recovery. Aromatic spirit of *ammonia* is an important adjuvant in straits like these, and may be substituted with advantage for the carbonate.

Inhalation of oxygen is of undoubted advantage in relieving the dyspnea and thus comforting the patient. Whether it is curative is much more doubtful.

High temperature may be reduced by sponging, though the temperature itself in pneumonia cannot be regarded as dangerous *per se*.

Should we ever blister in pneumonia? A blister in pneumonia sometimes does much good. It is especially useful in delayed resolution, late in the disease, where the crisis has been imperfect and convalescence does not set in. It may even take the place of a local or general blood-letting, especially when these have been deferred too long or are impossible from any cause. When a blister is applied, let it be an effective one. A large blister is no more painful than a small one, and neither is it so painful as is commonly supposed. In mild cases turpentine stupes may be sufficient to relieve pain.

I am well aware that pneumonia is regarded as a self-limiting disease, reaching its crisis in from five to nine days, and that many think the only indication is to sustain the patient until the crisis is reached. In many cases this is true, but I believe that the fury of the disease may be diminished by treatment, and that a prompt bleeding at a suitable time will not only lessen the suffering, and so spare the strength of the patient, but may also hasten the crisis. Another stage at which a blood-letting is sometimes serviceable is where the right heart, from its ineffectual efforts to propel the blood through the lung, becomes distended. Such a stage is indicated by intense cyanosis and gasping orthopnea.

The use of *veratrum viride* is warmly recommended by some instead of bleeding in the earliest stages of the disease. It diminishes the force of the heart, furnishes a diverticulum for the excess of blood, and, as my colleague, Horatio C. Wood, says, "The patient is bled into his own circulation." I have never felt comfortable in relying upon it.

The treatment of pneumonia by *ice-cold applications* has lately been gaining favor. Its most ardent supporters in this country are Simon Baruch, of New York City, and Thomas J. Mays, of Philadelphia. My experience has not been large, but it has been such as to encourage me to continue it. Further experience since the first edition of this book appeared

confirms my favorable impression. I prefer the method, recommended by Baruch, of enveloping the chest in a suitably fitted linen or muslin jacket (the ordinary cotton jacket answers well), wet in cold water at 60° F. (15.5° C.) and covered by a flannel bandage an inch wide and longer; directing that the jacket be removed and substituted by the dry cotton jacket whenever the temperature falls to 100° F. (37.7° C.), and renewed if the

Fig. 21.—Showing Drop in Temperature in a Case of Pneumonia Succeeding the Application of the Cold, Wet Jacket.

The figures opposite RESP. in upper left portion indicate the breathing rate, which was too rapid on admission to be indicated in the usual way by the chart.

temperature rises. In this way all danger is averted. Baruch recommends a preliminary dose of 15 to 20 grains (1 to 1.33 gm.) of calomel. Appended is the temperature chart of a case admitted to the University Hospital under my care, breathing at the rate of 58 a minute, and of whose recovery I had no expectation, but which passed to rapid convalescence after the application of the cold, wet jacket.

Dr. Mays prefers to surround the affected area with ice contained in bags that are wrapped in towels; but they are difficult to keep in place, especially when more than one bag is required, which is the case if more than a limited area is involved. He says, also, that if the temperature falls to the normal, or near it, with a tendency to remain there, the ice is to be gradually removed. The fever is, of course, a mere index of the severity of the disease, and it is not for the direct effect on it that the ice is applied, but to arrest the process. The effect of the ice is almost immediately to cause the temperature to fall. Such fall must not be mistaken for the crisis. If induced by the ice, it rises soon after its removal.

Hypodermoclysis of normal hot saline solution was used in desperate cases of pneumonia in the Philadelphia Hospital by Dr. Frederick P. Henry as early as the spring of 1889. Dr. Henry's first publication upon the subject, however, was made in January, 1900.* A few months earlier than this, Dr. Clement A. Penrose † published a paper on "Infusion of Salt Solution," etc., in pneumonia. The injection is made in the usual way, under the skin, at any stage in bad cases of pneumonia, from one-half pint to a pint (236 to 473 c. c.) of a .6 of one per cent. solution being injected daily. Dr. Penrose added that the treatment is more efficient when given in connection with oxygen inhalations associated with blood-letting if there is distention of the right heart as evidenced by cyanosis, flagging pulse, and sharp accentuation of the second pulmonic sound. The effect is that of a respiratory stimulant, reducing the pulse and breathing rate, as well as of a diluent for the toxins in the blood. Dr. Penrose also describes a method of inhaling oxygen which appears to be very satisfactory. In place of the usual delivery nozzle, a glass funnel is substituted, held about two inches from the face by a framework resting on the bed or an adjoining table. In this way oxygen is supplied to both mouth and nostrils without interfering with the breathing. These measures certainly merit a trial in desperate cases, the more especially as they are at least harmless, and add in no way to the discomfort of the patient, while the results claimed by both Dr. Henry and Dr. Penrose are most encouraging.

Serum Treatment.—Pneumonia was one of the first diseases the treatment of which by serum engaged attention. The subject was studied by the brothers G. and F. Klemperer, who utilized for prophylactic and curative purposes the antitoxin derived from the blood of immunized animals. Immunity is obtained by subcutaneous or intravenous injection of filtered bouillon cultures of the pneumococcus, cultures sterilized by heat or antiseptics. Such immunity is limited to six months, but the young born within this period are also immune, while the serum of the blood of such animals has the power to immunize other susceptible animals. Nay, more, these fluids, when introduced into the blood of animals already infected, were found capable of curing them. Thus, in such animals with a body temperature of from 104° to 106° F. (40° to 41° C.) the fever fell to normal in twenty-four hours after the injection of the serum. It is held by these experimenters that the pneumococcus produces a poisonous albumin or pneumotoxin, which when introduced into the circulation of an animal causes a rise of temperature, and later an antipneumotoxin, which has the power of neutralizing the poisonous albumin formed

* "Treatment of Pneumonia by Hypodermoclysis," "International Clinics," vol. iv., Ninth Series, 1900.

† "Johns Hopkins Hospital Bulletin," July, 1899.

by the bacteria. During the pneumonia the pneumotoxin produced by the bacteria in the lungs is constantly being absorbed into the circulation. In natural recovery this continues until enough antidotal substance is generated in the circulation to exert its effect when the crisis occurs. The bacteria are not destroyed, nor is their ability to produce poisonous products, but these latter are neutralized by the antitoxin, the presence of which has been demonstrated in the serum of the blood of pneumonia patients after the crisis. Klemperer first injected this serum into infected animals, with the effect of curing them. Finally, he injected into persons ill with pneumonia the blood serum from others convalescent from pneumonia, with a view to hastening the crisis. In six cases there was a decided reduction in temperature in from six to twelve hours after injection of from 65 to 95 minims (4 to 6 c. c.) of the serum. The pulse and respirations also fell. The serum has no effect when injected into healthy individuals.

Pneumonia antitoxin has continued to be used, from time to time, since its introduction by the Klemperers, but it has not established a reputation as a remedy superior to other methods of treatment in common use. It is made by the Mulford Company, in Philadelphia, whose dose is 20 c. c., or three dessertspoonfuls, beneath the skin, repeated in from four to six hours while the temperature exceeds 103° F. (38.3° C.), after which it should be given twice a day for several days. If the temperature is below 103° F. and there is severe constitutional disturbance, the injection should be continued more frequently until there is marked improvement.

This serum is produced by a method used by Pane, Washburn, de Renzi, Lambert, and McFarland by immunizing animals to increasing doses of live virulent cultures. McFarland has secured in the horse a tolerance to 100 c. c. of a very virulent culture. From such an antipneumococcus serum is obtained. I have used this serum in some 19 unselected cases, but am unable as yet to draw any conclusion from my observations.

BRONCHOPNEUMONIA.

SYNONYMS.—*Catarrhal Pneumonia; Capillary Bronchitis; Suffocative Catarrh; Lobular Pneumonia; Aspiration Pneumonia; Deglutition Pneumonia.*

Definition.—Bronchopneumonia is an inflammation of lobular or patchy areas of lung tissue caused by microbic or other irritants that find their way to it through a bronchus.

Etiology.—The effects of recent studies go to show that the bronchopneumonias of children are the result of the same causes as the lobar pneumonias of adults, producing however in the latter lobar consolidation and in the former lobular or patchy consolidation.* Usually bronchopneumonia succeeds a bronchitis of the terminal bronchus leading to the part. Some would consider bronchopneumonia and capillary bronchitis one and the same thing, but the latter term is best restricted to what it actually indicates— inflammation of the smallest bronchioles. It often precedes, and is often associated with, bronchopneumonia. Parts of a lobule, a whole lobule, or scattered

* See Samuel West, "Clinical Lecture on Bronchopneumonia," to show that pneumococcal pneumonia in a child takes the lobular and not the lobar form. Reprinted for the author from the "British Med. Jour.," May 23, 1893.

groups of lobules are thus affected, and may unite to form larger areas. Thus, while a bronchopneumonia is primarily lobular, we may have even a lobar bronchopneumonia if all the lobules of a lobe are simultaneously affected. Aspiration pneumonia is a bronchopneumonia caused by the irritation of inhaled or indrawn particles, including bacteria, among which must be included also streptococci and staphylococci, as well as pneumococci and tubercle bacilli. Tubercular bronchopneumonia is one variety of this. Syphilitic bronchopneumonia is a rare, but possible, affection.

The recognition of bronchopneumonia as a separate disease is usually credited to Barthez and Rilliet.

Simple bronchopneumonia is pre-eminently a disease of the very young and the old. In the young it occurs as an idiopathic affection, though it is also a frequent complication of the infectious fevers, measles, whooping-cough, scarlet fever, diphtheria, and smallpox. In adults, especially the old, it occurs during influenza, erysipelas, typhoid fever, and all debilitating affections, including Bright's disease and organic disease of the heart. The inhalation variety especially occurs in comatose states, however induced. William Pepper laid especial stress on vesicular emphysema as a predisposing cause. In both young and old it may succeed a simple bronchitis from cold, but it is as a complication of the infectious diseases named that it becomes during the first five years of life a very common, serious, and fatal disease, causing, it is said, more deaths among children than any other disease except infantile diarrhea. Diarrhea itself and rickets are also to be included as predisposing causes. All influences depressing to life, such as overwork, fatigue, the air of badly ventilated and crowded houses, insufficient food, and defects of hygiene act similarly. Collapse of the lung is at once a cause and a consequence of bronchopneumonia.

Another cause of bronchopneumonia more common in adults and the aged is the inhalation of fine irritant particles or the aspiration of particles of food. In comatose states from any cause the sensibility of the larynx is benumbed, and minute particles of food are permitted to pass beyond the rima glottidis to enter the larynx, and thence the smaller bronchial tubes, where they excite inflammation. Hence the term *aspiration* or *deglutition pneumonia*. Glossopharyngeal palsy is often associated with deglutition pneumonia, which may follow tracheotomy and cancer of the larynx and esophagus. The inflammation thus excited is sometimes so intense as to cause suppuration and even gangrene. Stone-cutting, steel-grinding, and coal-mining become causes through the irritating particles inhaled in these occupations. Francis Delafield, in the section on bronchopneumonia, in his "Studies in Pathological Anatomy," says the extension is not from the bronchus to the air-vesicles that are connected with it, but to those that surround it. Thus he says, "It is as if a red-hot needle were thrust through the lung, making a track of charred tissue around it." He refers more particularly to the bronchopneumonia that succeeds bronchitis.

Morbid Anatomy.—The morbid anatomy of simple bronchopneumonia is quite definite, yet somewhat complex and difficult of description. The lungs may be superficially unaltered or they may be large and heavy. On the exterior, especially at the base, may be seen a mottled appearance, due to an alteration of dark-blue or bluish-black depressed areas with projecting portions more natural in hue. The depressed areas represent collapsed lung, and can, for the most part, be reinflated. In places they are continuous, forming large patches. Where there is much of this diffuse

pneumonia, corresponding patches of fibrin may be seen on the pulmonary pleura.

On section the surface of the lung is dark red in color and from it project reddish-gray spots, representing areas of bronchopneumonia. These may be separated by tracts of uninflamed and collapsed tissue, or may unite to form more extensive inflamed areas. A section made transverse to the lobule will be found penetrated by a central bronchiole filled with muco-pus, while if the section is parallel with the length of the bronchiole, the central alveolar passage with its alveoli may be readily recognized, being rendered distinct by the same muco-purulent contents. Around the bronchus, to the extent of from 1-8 to 1-5 inch (3 to 5 mm.) or more, is an area of grayish-red consolidation elevated above the surface, usually slightly granular to the touch, but still lacking the hard, shot-like feel of croupous pneumonia. On pressure, a mixture of pus and desquamated cells may be squeezed out, which, at a later stage, becomes almost pure pus, appearing as white points in the non-depressed tissue. Surrounding the imperfectly hepatized areas and at a lower level is a smooth, dark, airless tissue, representing collapsed lung, which may be the seat of beginning inflammation. At a later stage, if the patient survives, especially in adults, the inflammatory areas may assume a darker hue, even that of gray hepatization. Still later, in the persistent forms, the areas may contain foci resembling miliary tubercles, from which they may be always distinguished by the fact that the white droplets can be squeezed out, while tubercle remains firm. These areas may be converted into cirrhotic patches. During the progress of a bronchopneumonia the air-cells in the adjacent lobules are found dilated, and the edges of the lung and upper portions have also become emphysematous. The bronchioles themselves are also dilated in places. The uninflamed areas are generally congested.

The contents of the bronchioles and air-vesicles are pus-cells and swollen exfoliated epithelium. The walls of the bronchiole and of the air-vesicles are thickened and infiltrated with leukocytes. Rarely do they contain blood or the fibrin-network characteristic of lobar pneumonia. Occasionally, minute extravasations of blood may be found.

The phenomena in the aspiration form of bronchopneumonia are more intense in every respect than in the other forms, the infiltration of the air-vesicles with leukocytes leading sometimes to suppuration or even to gangrene.

Symptoms.—The initial symptoms vary with the precursory disease. In a child—and here the disease has its greatest practical interest—there may have been measles or whooping-cough or diphtheria, in which convalescence may or may not have set in. To incipient or aggravated *cough* decided *fever* is added, a temperature of 102° F. (38.9° C.) and higher being attained; the cough becomes more severe and painful, the *breathing becomes rapid*, and an easily visible, distressing *dyspnea* supervenes. The embarrassed breathing grows worse, the fever is higher, the *lips* and *face become cyanosed*, the short, incessant cough is ineffectual in the raising of expectoration, and the little sufferer is a picture of pitiable distress. For such a state of affairs the term *suffocative catarrh* given by the older authorities is well chosen. Happily, as the disease advances and the blood becomes charged with carbon dioxide, sensibility wanes, the suffering abates, and the cough grows less; but the frequent breathing, often 60 to 80, the lividity of the face, and the frequent pulse show that the fury of the disease is not spent,

but will probably terminate only in the death of the little sufferer, which is directly due to exhaustion of the muscle of the right ventricle. At times, however, and even when least expected, a favorable turn takes place and a surprisingly rapid convalescence sets in.

In adults, as in children, the symptoms vary with the mode of origin. In the idiopathic form, which is recurrent in some old persons, there are fever, a burning spot in the cheek, and shortness of breath, but a cough less troublesome than would be expected. The physical signs rather than the symptoms determine the diagnosis. There are fine moist râles, with harsh breathing rather than bronchial breathing, and relatively clear percussion.

The symptoms in a case of deglutition pneumonia are very similar. In the inhalation pneumonia of miners, stone-cutters, and steel-grinders the symptoms are slower in their development and resemble more those of tubercular phthisis.

Physical Signs.—These are by no means as distinctive as those of croupous pneumonia. Though I think it best to separate capillary bronchitis from bronchopneumonia, the association is so close that, given the fine subcrepitan râles of the former, unaccompanied by impairment of resonance, we may infer that bronchopneumonia is at hand. Further signs, however, of actual involvement of the lung-substance are *moderate impairment of resonance* and *harsh* breathing, rather than true bronchial breathing, though more rarely the latter may be present, especially when the bases of the lung are involved. Inspection may recognize retraction of the cartilages and lower sternum during inspiration, indicating defective expansion of the lung.

Diagnosis.—The diagnosis of bronchopneumonia is usually easy. High fever, cough, mucous expectoration, fine râles, and slight impairment of resonance, following one of the infectious diseases in a child under five years, and developing gradually, admit of but one interpretation. When a number of small foci unite to form a large area corresponding to the whole or a portion of a lobe, the physical signs are more like those of a lobar pneumonia, and the absence of expectoration in children increases the difficulty of diagnosis. Lobar pneumonia develops more suddenly and resolves more rapidly.

The similarity in the morbid anatomy of persistent bronchopneumonia and tuberculosis has been referred to, and the clinical resemblance is even greater, so that it may be impossible to say of a given condition in a child which it is. The presence of signs at the apices is to be sought for, and, if found, tuberculosis may be suspected; but the correct diagnosis is sometimes made only on the autopsy table.

Prognosis.—The prognosis varies with the etiology, but bronchopneumonia is always a serious disease. From 30 to 50 per cent. of all children perish from it.

In fatal cases in children death may occur in twenty-four hours. When recovery takes place, the disease lasts from five to ten days, and as many more are required for complete restoration to health. More rarely a chronic interstitial pneumonia, what Delafield calls a persistent bronchopneumonia, develops, which may last for months or years and finally give rise to miliary tuberculosis.

Yet, as mentioned under symptomatology, some remarkable recoveries take place. In adults it is about as serious as croupous pneumonia. The

deglutition variety is almost always fatal, and is the usual cause of death in glossopharyngeal palsy. Some cases pass into tubercular consumption, even in children.

Treatment.—The indifference of parents and the carelessness of nurses are responsible for many cases of bronchopneumonia occurring during convalescence from measles, diphtheria, and whooping-cough which, with proper care, might have been averted. Among the causes thus responsible are exposure of children with uncovered heads at open doors and windows, insufficient clothing during sleep, overheated rooms, and drafty corridors.

Restorative measures are indicated in this disease from the outset. Nauseating expectorants are rarely demanded and often do harm by lowering the vitality of the young patient. Blood-letting, undoubtedly useful in some cases of croupous pneumonia, is not called for in catarrhal. Opiates to quiet the cough and relieve the pain are the strongest indications in the earlier stages of the disease and sometimes throughout it. They should be associated with diaphoretics and febrifuges, among which the solution of acetate of ammonium, the solution of citrate of potash, and sweet spirit of niter are the best. The tincture of aconite in small, but often repeated, doses is extremely valuable if the temperature is high and the pulse full and rapid.

When secretions become free and a stimulating expectorant is required, there is none better than the aromatic spirit of ammonium, which fulfills every indication and spares the stomach more than the chlorid or carbonate of ammonium. If the accumulation of mucus become troublesome, it may be dislodged by a mineral emetic, such as alum, of which the dose for a child is a heaping teaspoonful; or sulphate of zinc, in doses of 10 to 30 grains (0.65 to 2 gm.); or the syrup of ipecac., more likely to be at hand, may be used. At this stage, alcohol, in the shape of whisky or brandy, becomes an important adjuvant. It should be added to the nourishment, of which the best form is milk, although nourishing broths are also indicated. As digestion is likely to be feeble, the milk is better peptonized. Quinin, and especially strychnin as a respiratory stimulant, are useful tonics.

In the way of local treatment counterirritation by mustard and turpentine is especially useful. The former should be used in the shape of a weak plaster, one part of mustard to five or six parts of flour or flaxseed meal. If white of egg and glycerin be used to mix it instead of water, the plaster is less painful and may be kept on continuously. One of the best modes of applying turpentine is by the St. John Long liniment, which may be made by mixing thoroughly a teacupful of vinegar, a wineglass of turpentine, and one egg. This may either be rubbed thoroughly on the chest or it may be applied on flannel. It may be that the turpentine is absorbed and acts as an expectorant. Blisters are not to be recommended.

The poultice is a measure of treatment for catarrhal pneumonia which is variously valued. It is undoubtedly useful in children if properly employed, but great care should be taken that it does not become cold. It should be lightly made and changed often; and when changed, it should be done rapidly, a fresh, hot poultice being at hand to replace the one removed. When poultices are not used, the cotton jacket should be substituted, as it insures a uniform temperature of the body. This should be further favored by maintaining a uniform room-temperature of 70° F. (24.5° C.) and averting drafts by screens.

If the temperature be very high, it may be reduced by sponging, or, better, by the wet-pack at a temperature of 75° F. (25° C.). The child

does not, however, die of the effects of high temperature, but rather, finally, of a failing right heart. The bath is, nevertheless, very calming to the nervous system, and should be used for this reason.

The same measures may be used with appropriate modifications in the catarrhal pneumonia of adults, and also in the variety known as deglutition pneumonia. As this last form of pneumonia is, however, generally the beginning of the end in some other serious condition, treatment avails but little.

CHRONIC INTERSTITIAL PNEUMONIA.

SYNONYM.—*Cirrhosis of the Lung.*

Definition.—A chronic inflammatory disease consisting in a gradual invasion of a lung by fibroid tissue, with a corresponding reduction in the vesicular structure of the lung. According as it involves limited or more extensive areas it is local or diffuse.

Etiology.—Interstitial pneumonia is mainly a secondary affection. There are few chronic affections of the lung which do not cause a certain amount of fibroid overgrowth. Especially is this true of tubercular consumption and bronchopneumonia. A form of the latter is the so-called *pneumoconiosis*, a fibroid induration succeeding a bronchopneumonia due to the irritating effects of minute particles arising in the occupations of coal-mining, stone-cutting, steel-grinding, and iron-working in general. To the form associated with tuberculosis the term fibroid phthisis is applied, and it has received separate consideration. The seat of a healed tuberculosis is also occupied by fibroid tissue, which may be regarded as an example of interstitial pneumonia. Less frequently it succeeds croupous pneumonia as fibroid induration, which has been considered on page 221 and constitutes an important product in pleurogenic pneumonia mentioned on page 222. Even abscesses of the lung may excite it, while the various forms of morbid growths, as sarcoma, carcinoma, chondroma and hydatid cysts, are causes of it, and are surrounded by fibroid growths. Especially does the fibroid change occur in a lung that has been long in a state of compression, as by a pleuritic effusion. Since the majority of cases of chronic interstitial pneumonia are directly or indirectly the result of microbic agents, it has appeared to me best to retain its consideration in this section, even though some cases may be due to other causes.

Morbid Anatomy.—*Pathological Histology.*—In bronchopneumonia the fibrosis usually starts from the outer sheath of the bronchi, invading the alveolar walls and converting the entire lobule into grayish fibroid tissue, in which no lung structure is distinguishable. This form is frequently associated with dilated bronchus, of which the fibrosis is probably the direct cause, its contraction drawing the walls apart. The line of demarcation between interstitial pneumonia on the one hand and tuberculosis on the other is often not very sharp.

In interstitial pneumonia after croupous pneumonia a gradual organization takes place of the fibrinous plugs in the air-vesicles: the alveolar walls themselves become thickened by a new formation, at first cellular and subsequently fibrillated. Death usually occurs in these cases in one to three

months after the onset of the disease. The whole of the part primarily invaded may become thus altered.

Macroscopic Morbid Anatomy.—The chest-walls of the side affected are often depressed, and on opening the thorax, the lung, or as much of it as is involved, is found retracted; it may be drawn back into the spinal gutter. If on the left side, the heart may be retracted with it. Commonly the two pleuræ are found united, but not always. On section the lung is hard and tough. It is gray, fibrous, and the alveolar structure has, to a varying extent, disappeared. The bronchi and the blood-vessels, however, remain, the former being often dilated, to produce the so-called bronchiectatic cavity, of which there may be a number. The pulmonary artery may be atheromatous. In the phthisical variety there may also be a cavity at the apex, and a recognition of this before death will be an aid to diagnosis. Otherwise a careful study is often necessary to distinguish the two varieties, unless the tubercle bacillus has been found.

The uninvolved lung is usually enlarged and emphysematous in proportion to the degree of contraction of the affected lung. The right ventricle, which has increased work imposed upon it in forcing the blood through the contracted lung, becomes hypertrophied and may become ultimately dilated.

Symptoms.—The principal symptom is *cough*, which starts with the condition causing the fibrosis and continues to the end. It varies greatly in its severity, being sometimes trifling, at others very troublesome. The *expectoration* is as variable as the cough; more copious as the cough is more troublesome. Persons thus affected have the appearance of delicate health, and are commonly regarded as phthisical, although they have often considerable strength and can pursue some occupation. In non-tubercular interstitial pneumonia there is less *fever* than is present as a rule in phthisis, but the recognition of the tubercle bacillus is the crucial test, for otherwise the symptoms are very similar. In both conditions there is paroxysmal cough, with copious expectoration of muco-purulent matter. The resemblance is still more close if there is bronchiectasis, when the usual emptying of the cavity by cough takes place, commonly in the morning, sometimes twice a day, and even oftener. The expectorated matter of the bronchiectatic cavities may be fetid from decomposition. There is usually less dyspnea than in true phthisis, and except where the disease is the sequel of true pneumonia, the fatal termination is longer deferred than in tuberculosis—it may be for years.

Physical Signs.—The chest is more or less retracted, its circumference diminished. Its movements are restricted and its topography altered. When the left lung is extensively affected, a pulsation is often seen in the second, third, and fourth interspace, very similar to what is sometimes seen in the right of the sternum, when a pleuritic effusion on the left side pushes the heart over to the right. It is probably the result of rhythmic retraction and relaxation of the interspaces corresponding to the cardiac action due to adhesion. In high degrees of the disease the shoulder is drawn down and the spinal column laterally curved, just as in recovery after empyemic pleurisy. The unaffected side is more prominent than in health. The tactile fremitus may be diminished or increased according as the pleural membrane is thickened or not. The same is true of vocal resonance. Percussion generally elicits impairment of resonance over the affected lung, though there may be high-pitched tympany and even amphoric resonance over a dilated

bronchus. The lung on the sound side furnishes hyperresonance. To auscultation the breathing sounds may be feeble, but there may be bronchovesicular or bronchial and even amphoric breathing of the most intense kind.

There is usually sharp accentuation of the second pulmonic sound because of the forcible effort of the right ventricle to push the blood through the contracted lung; and when the right ventricle begins to yield, cardiac murmurs may develop at the tricuspid valve.

Diagnosis.—Chronic interstitial pneumonia is mainly to be distinguished from fibroid phthisis, which is often impossible without an examination of the sputum for bacilli. The history and duration of the case may be of assistance.

Prognosis.—Recovery is impossible, yet cases last many years—ten, fifteen, and even longer.

Treatment.—As intimated, treatment for the fibrosis is unavailing, though lung gymnastics should be practiced with a view to developing lung expansion. Intercurrent bronchitis may be helped by the usual remedies for that disease. Antispasmodics, belladonna, and hyoscyamus are often useful adjuvants to the cough medicines. Patients are generally better in summer and in a warm climate, where they should dwell, if possible. They should be fed with an abundance of rich, nutritious food, and surrounded by the most favorable hygienic conditions.

EMBOLIC PNEUMONIA.

Definition.—An embolic pneumonia is a pneumonia caused by an embolus, or, more rarely, by a thrombus formed in the pulmonary artery. Embolic pneumonia is either non-septic or septic.

EMBOLIC NON-SEPTIC PNEUMONIA.

SYNONYM.—*Hemorrhagic Infarct of the Lung.*

Etiology.—The non-septic hemorrhagic infarct of the lung is the result of embolism, more rarely of thrombosis, of the pulmonary artery. The emboli come from the right side of the heart, where they either originate as fragments of thrombi or have entered from the systemic veins. Emboli usually lodge at the bifurcation of the branches of the pulmonary artery. The usual transudation of blood takes place in a cone-shaped area. Not every embolus is followed by an infarct. An embolus may be so large as to cause death before an infarct can be formed. Nor is every hemorrhagic infarct followed by a pneumonia. The ultimate consequences of non-infectious emboli depend on their size. A large embolus and a corresponding infarct with free extravasation of blood are liable to be followed by gangrene of the lung, which may excite intense reactive inflammation in its neighborhood, and the aspirated blood may cause pneumonia. When the lodged particle is small, the hemorrhagic infarct is small, and the transudate is a diapedesis rather than a hemorrhage. From this, true embolic pneumonia results only when there is no collateral circulation—that is, when it is supplied by an end-artery.*

* All the large branches of the pulmonary artery are end arteries, and many of the smaller branches also.

Morbid Anatomy.—The infarct thus caused is conical in shape with its base toward the pleura, and varies in size from that of a cherry-stone to that of a hen's egg. The pleura over the infarct at first projects above the surrounding surface, and is at first smooth, but later is roughened by a film of lymph. The infarct when recent is dark reddish-brown in color, and on section rises also above the surrounding surface.

This transudation is the preliminary of a peculiar reactive inflammation—the embolic pneumonia under consideration. Succeeding a slight preliminary contraction there takes place an immigration of leukocytes from the contiguous vessels which accelerates the reabsorption of the blood. To the disintegration and absorption of the red blood-discs succeed a more rapid paling and contraction, until no color remains, or there may be a hardening of the pulmonary tissue, with a cicatricial-like contraction, into which the pleural membrane is drawn, producing fibroid thickening with radiated prolongations. Such hardening is partly due to a condensation of the lung and partly to an organization of the cells in the infiltrated alveoli and alveolar walls. Such remnant is slate-gray from the residue of hematin derived from the extravasated blood, or it may be dark red, owing to hematoidin crystals throughout it. If the infarct is large, a part may break down into reddish inodorous pulp, which may be absorbed, or a part may make its way into a bronchus and may be expectorated. In the event of so large an infarct the residue of cicatricial tissue is larger. Caseation and calcification of the remains are possible results.

The embolus itself is in like manner removed, a few filaments or slight wrinkles in the walls of the vessel being the sole residue.

Symptoms.—There may be no symptoms, or these may be confined to a transient *pleuritic pain* in the pleura covering the embolus. With the increase in size of the infarct such pain increases, and may be associated with some *shortness of breath*, due to destruction of the aërating surface. To this may be added *expectoration of blood* if the effused blood gets into the bronchus. If the infarcted area be sufficiently large, there may be dullness on percussion, increased vocal fremitus and resonance, crepitant and subcrepitant râles, bronchial breathing, and bronchophony. Further characteristics are the absence of fever and suddenness of onset and the presence of intravascular disease. It has been mentioned that the embolus may be so large, and cut off so large a supply of blood to the lung, that death will take place before an infarct can form.

Diagnosis.—Embolic non-septic pneumonia is often overlooked. The foregoing symptoms, suddenly occurring in connection with states leading to thromboses in the veins or the right heart, may be suspected to be due to non-septic embolic pneumonia. Infarcts that form in the lung from non-infectious emboli arising in the *left* heart or arterial system must be so small as to escape detection, since the emboli themselves must be so small as to pass through capillaries into the veins, thence into the right heart, and thence to the lung.

Prognosis.—The prognosis of non-septic embolic pneumonia is favorable unless the embolus is so large as to stop up a large vessel, producing a correspondingly large infarct. An embolus plugging one of the largest branches of the pulmonary artery is fatal before an infarct can form.

Treatment.—Nothing can be done actively to relieve an embolic pneumonia of this kind. A patient in whom it is suspected must, of course, be

kept absolutely at rest. Counterirritation may be applied to the chest-wall over the area involved. Anodynes should be used to a degree required to relieve pain.

EMBOLIC SEPTIC PNEUMONIA.

SYNONYM.—*Metastatic Abscess.*

Etiology.—The cause of septic pneumonia or metastatic abscess of the lung is a septic embolus. Such a septic embolus may originate in a thrombus at a seat of putrid inflammation or suppuration, such as the wound of an operation or a compound fracture, or in the uterus after childbirth. The veins of such a focus are filled with thrombi, which extend into the larger branches, where they soften and break up into fragments, some of which may pass into the right heart, thence into the pulmonary artery and its branches, until one is reached small enough to resist its further transit. Such an embolus, which is probably swarming with bacteria, is an intense irritant, and inflammation sets in that invariably terminates in abscess, as contrasted with the simple indurative irritation caused by a non-septic embolus. Thus caused, septic pneumonia is one of the anatomical features of pyemia.

Morbid Anatomy.—Should it be our fortune to see this form of pneumonia in its first stage, the same dark-red color as that seen in the hemorrhagic infarct of non-septic pneumonia may be noted, except that the blood extravasation is more copious. Such extravasation is a further irritant, and soon an intense inflammation sets in, which may also be divided into two stages. In the first stage the alveolar spaces and the connective tissue of the alveolar and infundibular walls are infiltrated with pus-cells. The latter furnish a white-gray ground, on which may be seen, with the naked eye, delicate red lines and circles, which represent infundibula whose vessels are still pervious to blood. In the next stage abscess-formation rapidly succeeds, when the hepatized area melts into a creamy pus, in which float a few fragments of elastic tissue representing broken-down alveolar walls and blood-vessels. The abscesses thus produced may be multiple, but are mostly of small size. If the abscess is subpleural, there will be suppurative pleuritis with empyema, and possibly perforation of the lung.

In case a very large vessel is obstructed and a corresponding part of lung cut off, say a fifth of a lobe, the area thus deprived of pulmonary arterial blood is rapidly filled from the veins, and a condition analogous to a hemorrhagic infarct occurs, to the border of which the inflammation is confined, where finally the necrotic mass is dissected loose.

Symptoms.—The symptoms are those of pyemia (see p. 181), of which the lung abscesses form a part. A *chill* succeeding a surgical operation of occurring during the lying-in state, followed by *sweating* and *high fever*, are significant symptoms. Successions of these are even more conclusive.

Treatment.—Treatment should be supporting and stimulating. Quinin should be administered in large doses, and whisky as in a low fever. The physician should watch for an opportunity for surgical interference, although such opportunity rarely occurs.

TUBERCULOSIS.

I. GENERAL ETIOLOGY AND INVASION. MORBID ANATOMY.

Definition.—Tuberculosis is a general or local infectious inflammatory disease, the result of the implantation and proliferation of the tubercle bacillus. The action of the tubercle bacillus is peculiar in that it stimulates the cells of the body wherever it may lodge and grow, to the formation of little masses of new tissue which are called *miliary tubercles*. A miliary tubercle may, therefore, be defined as a nodule of new formation around an irritated point, the focus of which is the tubercle bacillus.

The tubercle bacillus is a short rod-bacterium three to four microns in length, equal to about 1-3 the diameter of a red blood-disc, and 1-6 to 1-5 as broad as it is long. When successfully stained and viewed with high power it presents at times a beaded appearance once ascribed to the presence of spores, but now, I believe, regarded as the result of unequal staining. It can be studied satisfactorily only when stained by one of the anilin dyes.*

Etiology.—Although the evidence in favor of the bacterial origin of tuberculosis may be regarded as conclusive, the readiness with which the bacillus lodges and grows varies greatly; indeed, the number of instances in which it fails to take root doubtless vastly exceeds that in which it does. Hence, the contagiousness of tuberculosis is slight and, although there appears to be no difficulty in transmitting the disease from one domestic

* Of the various methods of staining tubercle bacilli that by the carbol fuchsin solution of Ziehl-Neelsen, with or without Gabbet's counter-stain of methyl blue, continues to be, on the whole, the most satisfactory. By this method the bacillus takes a bright-red color from the fuchsin, the mordant being carbolic acid.

The carbol fuchsin solution is made as follows:

Powdered fuchsin.....	1 part
Alcohol.....	10 parts
5 per cent. solution carbolic acid.....	100 parts
Mix and filter.	

The older the solution the better.

A rapid and a slow method are practiced with this staining fluid, the former being more commonly used for diagnostic purposes.

1. *The Rapid Method with Carbol Fuchsin, with or without Counter-stain, by Methylene Blue.*—A very small caesated clump of the sputum (care being taken that a bit of food is not taken by mistake) is selected with forceps or a platinum loop and laid on a clean cover-glass. Another cover-glass is superimposed and the two are rubbed together until the specimen is thoroughly smeared over both. They are then separated, two specimens being thus obtained. When dry, one of them is passed, sputum side up, three times over the flame of a spirit lamp or Bunsen burner, by which the albumin is coagulated and the specimen is fixed. The cover-glass is then completely covered with the staining fluid and held over the flame until the solution begins to vaporize, care being taken to keep all parts of the glass thoroughly covered. At the end of one minute it is washed in water. It is then decolorized in acidulated alcohol, 8 to 10 gtt. of HCl or 5 gtt. of HNO₃ to a watch crystal of alcohol, and examined. For this a 1-12 oil immersion lens and Abbé's condenser are best suited, but after a little experience an ordinary dry system of 350 diameters' amplification, or higher, will easily reveal the bacilli, which are stained a handsome red.

The preparation is more brilliant and its study rather less trying to the eyes if counter-stained by a Gabbet's acid blue, composed of—

Methylene blue.....	2 parts
25 per cent. solution sulphuric acid.....	100 parts

After being washed in water the specimen is immersed for one-half to two minutes in the acid blue, washed off in water, dried between folds of filter paper, and examined in water.

2. *Slower Method with Carbol Fuchsin and Counter-stain by Gabbet's Acid Blue.*—This slower method is always more satisfactory, if time permits, and should alone be used for permanent preparations.

The steps are the same until the staining stage is reached, when the cover-glasses containing the specimen are placed in the carbol fuchsin solution, say at five or six o'clock in the evening, and allowed to remain until next morning. They are then washed in water, counter-stained by Gabbet's acid blue solution, washed in water, dried between folds of filter-paper, and studied in water; or, if it is desired to mount the specimen permanently, it is passed through alcohol, xylol, or oil of cloves into Canada balsam. Specimens stained in anilin colors should not be mounted in glycerin, as this gradually withdraws the stain.

When bacilli are very few, in viscid sputum, the centrifugator may be used, or Biedert's method pursued. Fifteen c. c. of the sputum are mixed with 75 to 100 c. c. (about two teaspoonfuls) of water, 4 to 8 gtt., according to the density of the fluid, of liquor potassæ are added, and the whole boiled. If still very viscid, add gradually, while boiling, 4 to 6 teaspoonfuls more of water, until a thin fluid results. The mixture is allowed to stand in a conical glass for two days, when the supernatant fluid is removed and the sediment is examined as before. It is to be remembered that bacilli treated with alkalis stain slowly, and longer immersion in the staining fluid may be necessary on this account.

animal to another, it is with extreme rarity that a case of tuberculosis in a human being can be traced to another. In an experience of thirty-five years, including large general hospital service, I can recall but a single instance of probable communication of the disease, and this was from a husband to the wife who was his faithful nurse for years. It would seem, however, that the contagium is more active than such experience would lead one to suppose. Thus, Cornet studied the records of certain institutions whose inmates are devoted to nursing, and discovered the fact that a large proportion of these (62.8 per cent. in twenty-five years) died of phthisis; also that of 100 nurses 63 died of this disease. It is to be remembered, however, that the life of the Sisters in convents is unwholesome from too close confinement. On the other hand, the statistics of the Brompton Hospital for Consumptives in London is decidedly against any conclusion that contact with patients peculiarly endangers the lives of doctors, nurses, or attendants. This, too, though they cover a period when no precautions were taken to destroy the bacillus.

Flick's studies also point to a greater activity of the contagium than is usually admitted. He examined all of the houses in a ward in Philadelphia where there had been deaths from consumption, and found that 33 per cent. of such houses had more than one case, that 25 per cent. of these houses had been infected prior to 1888, and that more than 33 per cent. of the deaths which occurred since 1888 took place in them. These observations accord with the results of Cornet's experiments, which demonstrated that the scraping from the walls of phthisical wards inoculated into the lower animals produced tuberculosis.

A truly remarkable experience of Reich is related by Eichhorst.* In the town of Neuenburg, containing 1300 inhabitants, the midwifery cases were about equally divided between two midwives. One of these contracted consumption. She was in the habit of blowing from her mouth into the air passages of the new-born children, with a view to clear away the mucus. Within two years ten of the children delivered by this woman died of tubercular meningitis, while of the children delivered by the healthy midwife none showed any sign of tuberculosis.

The conditions which favor the growth and multiplication of bacilli have been carefully studied, but have been only partially determined. One of the best recognized of these,

Heredity, is much more influential when both parents have the disease than when one is affected. It seems to be true that the child resembling a tuberculous parent is more liable to the disease than one who resembles the healthy parent.

A second favoring condition is *scrofulosis*, or the "delicate constitution." The peculiar enlargement of the lymphatic glands, formerly known as scrofula, is now regarded as true tuberculosis of those glands. There remains, however, a condition called scrofulosis, characterized by paleness, softness, and translucency of the skin of its subject, in whom inflammations run a slow course, and tend to resolve slowly and to terminate in cheesy products. To this some, and notably Rindfleisch, would still apply the name scrofulosis or the tuberculous diathesis. In these the tubercle bacillus finds a favorable soil. On the other hand, there is a tradition that persons affected with tuberculosis of the lymphatic glands are less prone to tuberculosis of the lungs than others.

* "Pathologie und Therapie," vol. 1. p. 559.

Defective and insufficient food, especially when associated with imperfect ventilation, privation, grief, and overwork, are also conditions which favor the growth of the bacillus.

Frequently recurring bronchial catarrh by lowering the vitality of the mucous membrane engenders a soil favorable to the growth and multiplication of the tubercle bacillus. Any of the causes that produce such catarrh may be included among predisposing factors. Particles of dust inhaled in the pursuit of various trades and avocations, as in coal-mining, stone-cutting, and steel-grinding, are well known to have this effect. Measles, whooping-cough, and typhoid fever with bronchial complications are sometimes followed by it.

Damp localities favor the development of tuberculosis, and the very interesting observations of H. P. Bowditch, made a number of years ago, show that in houses thus situated case after case occurs, and whole families have been swept away. It is more than likely these results are dependent on a vulnerability engendered by the "colds" and catarrhs which such localities induce.

No race is exempt, but the colored race is especially predisposed, as is also the American Indian when brought under the influence of civilization. Tuberculosis appears to be spreading among the Indians, even in districts in the Rocky Mountains where the disease is rare among the whites. It has been said that tuberculosis affects in the shape of the mild or severe form of pulmonary tuberculosis one-half of the whole human race, that it causes the death of one-seventh of all persons who pass away, killing one-third of those who perish between the ages of fifteen and forty-five. The Irish race in this country is also susceptible and many die of it. On the other hand, the Russian-Polish Jews are remarkably exempt, and next to them are the native American whites. I am indebted to W. A. King, Chief Statistician of the United States Census Bureau, for the following advance figures as to the nationality of victims of this disease:

	Six years 1894-1897	Calendar year 1900.
Total,	303.8	259.6
White,	385.1	250.6
Colored,	774.2	654.1
White persons having mothers born in:		
United States,	205.1	151.8
Ireland,	645.7	526.1
Germany,	323.8	214.2
Russia and Poland,	93.2	83.5

Over 6000 die annually from tuberculosis in Pennsylvania alone; while in the United Kingdom of Great Britain and Ireland 60,000 die annually from tuberculosis, and it is probable that at least three times this number are suffering from one form or another of the disease.

Climates characterized especially by frequent rapid changes of temperature favor the development of tuberculosis. Such are the temperate zones. Tuberculosis is less common in the frigid and torrid zones, but these climates are not exempt.

Age is doubtless a predisposing cause, the susceptible period for pulmonary tuberculosis being between twenty and thirty-five; for meningeal tuberculosis, between two and seven; while the lymphatic glands, including the mesenteric and bronchial, are prone to involvement in the first ten years of life. The mesenteric glands are more commonly infected during

the first five years of life, including the nursing period and that during which the child is nourished on milk.

The *shape of the chest* has long been regarded as influencing the development of tuberculosis, and a form of body peculiar to phthisical subjects was described by Hippocrates (B. C. 460-357); Galen (A. D. 130-200) described the same type of chest. At the present day two varieties of chests are described as phthisical, the *alar* and the *flat*. The former is narrow, shallow, and long, the angles of the scapulæ projecting like wings behind, the proper ratio between the antero-posterior and transverse diameters-being, however, preserved. The ribs droop or are unduly oblique. The throat is prominent, the neck long, and the head bent forward. In the flat chest the antero-posterior diameter is disproportionately short, owing to the absence of convexity in the cartilages, which are sometimes even depressed, carrying with them the sternum and producing a form of chest which, on section, is kidney-shaped. In this form there is not the increased obliquity of the ribs characteristic of the alar chest.

Traumatism is also an agency of acknowledged importance in favoring the lodgment of the tubercle bacillus. This is more particularly seen in the development of tuberculosis of the joints succeeding injury. It is true, also, that contusion of the chest, without apparent laceration of the lungs or fracture of a rib, has been followed by tuberculosis.

Mode of Invasion and Spread.—The bacillus of tuberculosis is probably omnipresent in the atmosphere, being derived from the drying and pulverization of expectorated sputum. The entrance into the body in the vast majority of instances is by the respiratory tract. Hence the great frequency of tuberculosis in the lungs and bronchial glands, which are the first tissues open to its approach. It is possible, however, for it to enter by the skin, causing lupus or skin tuberculosis. It enters more readily by open wounds. Through the alimentary canal we have an undoubted route of infection. This happens most frequently in children from the use of the milk of tuberculous cows*; in adults, from the swallowing of sputum. It is not necessary that the cow should have tuberculosis of the udder to render her milk tuberculous. This has been conclusively shown by Bollinger and confirmed by Hirschberger and Harold Ernst. The boiling of milk destroys its infective qualities. Tuberculous meat is less frequently the cause of tuberculous infection by the intestine because it is almost invariably cooked before eating, and also because striated muscular tissue is an infrequent seat of tuberculous lesions.

The tubercle bacillus having once invaded an organ produces localized tuberculosis, which may or may not become generalized in a manner to be presently described. More rarely, tuberculosis may become general from the onset without any local initial lesion being discoverable. This constitutes one of the varieties of acute tuberculosis. Once established, tuberculosis spreads by contiguity and through the lymphatic system and blood. In the former the tubercle grows by the addition of miliary tubercles at its periphery. Through the lymphatic system tuberculosis spreads to the lymphatic glands, and thence to the adjacent serous membranes. The barrier of the lymphatic glands once passed, the blood becomes the medium of a general infection. In the vast majority of cases generalization takes

* At the meeting of the Association of American Physicians, Washington, May, 1866, Theobald Smith, in a noteworthy paper on "Two Varieties of Tubercle Bacilli from Mammals," said he thought infection of the human subject through the milk of cattle decidedly questionable, and that the subject should be reinvestigated.

place from a focus of tubercle somewhere in the system, as the lungs, or a tubercular lymphatic gland, from which the bacilli start their migration.

The favorite seats of tuberculosis are the lymphatic glands, lungs, liver, kidney, spleen, intestinal canal, urogenital mucous membranes, the brain (especially its membranes and blood-vessels), the bones and joints. In fact, no tissue or organ is exempt, the salivary glands and pancreas being least frequently invaded.

Anatomy and Histology of Tubercle.—The *miliary tubercle* is the beginning of all tubercular deposits. It is itself a compound body composed of smaller submiliary tubercles, of which from 10 to 50 unite to form a miliary tubercle. It is about the size of a millet seed, hence the name miliary. By actual measurement it ranges from 1 to 5 millimeters (1-25 to 1-5 inch) in diameter. In its young state it is a translucent gray granulation, especially characterized by its want of vascularity. The typical submiliary tubercle is about 0.4 millimeter (1-60 inch) in diameter, and contains a giant cell in its center, surrounded by a close infiltration of lymphoid cells or a higher tissue of the lymphadenoid connective-tissue type, in the meshes of which are lodged loose lymph corpuscles or larger epithelioid cells. The giant cell may be wanting, and the whole tubercle may be a mass of lymphoid cells, among which the tubercle-bacilli are scattered, or the bacilli may be found in the giant cells, in the epithelioid cells, or even in the lymph cells. When isolated the miliary tubercle is found surrounded by a dense connective-tissue network, welding it firmly to the other tissues in which it is imbedded. The miliary tubercle is further characterized by its want of vascularity. In thin sections of an injected preparation it will be found that the blood-vessels go up to the tubercle and there terminate abruptly. To this lack of vascularity the tubercle owes its tendency to cheesy degeneration, in the course of which it assumes an opaque white color. When this happens, the center exhibits under the microscope a granular, ground-glass appearance, while macroscopically tubercle in mass assumes a yellow color.

In certain situations, especially in the lungs, the miliary tubercle forms larger foci, which gradually increase in size and constitute tubercular infiltration, the yellow or crude tubercle of Laennec (1819²) and Louis as contrasted with the miliary or gray tubercle. According to these and other observers during the first thirty or forty years of the present century, gray and yellow tubercles were simply differing forms of tubercle. Later, however, the influence of Virchow, Buhl, and Niemeyer (1857-70) caused it to be quite generally accepted that the only tubercle was the gray granulation or miliary tubercle, while yellow or crude tubercle was nothing but cheesy inflammatory matter. The subjects of this were still regarded as having phthisis, but not tuberculosis, whence the celebrated declaration of Niemeyer (1866), "The greatest danger to most phthisical patients is the development of the tubercle."*

Even before the discovery of the bacillus by Koch, in 1882—a discovery that resulted in the re-establishment of the unity of phthisis—the view began to gain ground, especially through the teachings of Buhl and Rindfleisch, that cheesy matter may be metamorphosed true tubercle, or it may have been primarily scrofulous inflammatory deposit, either of which might produce tubercle by an auto-inoculation. In the meantime, in 1865, Villemin announced the inoculability of tubercle. The discovery of the bacillus by Koch, in 1882, completed the overthrow of the duality of

* Niemeyer's "Lectures on Phthisis," New Sydenham Society's Translation, 1870, p. 11.

phthisis, the final result of which was the proposition, now generally admitted, *that all phthisis is tubercular*.

The *histogenesis* of tubercle is in no way peculiar. We have only to remember that the bacillus is an irritant. The same response occurs to it as to other irritants. The wandering leukocytes flow from the adjacent vessels and form the lymphoid cells that constitute the bulk of the tubercle. The stable cells of the connective tissue, the endothelial and perithelial cells of the blood- and lymph-vessels, the epithelium of the serous membranes, proliferate and enlarge, forming the epithelioid cells, and, in some instances, the giant cells, in both of which bacilli may be imbedded. The bacilli seem, however, to vary inversely with the giant cells. Thus, in lupus, joint and lymphatic gland tuberculosis, giant cells are numerous and bacilli scanty, while in lung tuberculosis bacilli are numerous and giant-cells scanty.

The reticulum of connective tissue, usually more or less present at the periphery of the miliary nodule, is formed just as is connective tissue in ordinary non-specific inflammation, by the fibrillation of the protoplasm of cells and the rarefaction of the resulting matrix.

The *origin of giant cells* has been much discussed, but it seems likely that any one of the connective-tissue cells named is capable of developing into a giant cell. It may also perhaps arise from the fusion of individual cells. It contains from 4 to 20 nuclei, commonly arranged in the periphery of the cell.

Another form in which the tubercle presents itself is the *solitary tubercle*, which is not made up of united miliary nodules, but consists of a single large, cheesy mass varying in size from that of a pea to that of a human fist. It is almost invariably secondary to primary tuberculosis somewhere else, commonly in the lungs. It is made up chiefly of round cells, in which are found also tubercle bacilli. In the peripheral layers a tissue of more fibrous structure prevails, which in certain tubercles becomes so abundant as to give rise to the term "fibrous tubercle." In addition to caseation the solitary tubercle is subject to puriform liquefaction, forming the so-called tuberculous abscess, and also to calcification. The two processes last named may be associated in a single solitary tubercle. Sometimes it is encysted. An especially favorite seat for solitary tubercle is the brain in children, especially the cerebellum at the border between the white and gray substance. The nodules are sometimes multiple. It is found also in the spinal cord, the spleen, the liver, and the heart.

Degeneration of Tubercle.—Tubercle is subject to changes, of which the most frequent and characteristic is *caseation*. It is a regressive change, whereby the primarily transparent tubercular tissue is converted into an opaque yellowish substance of various degrees of consistency, resembling certain varieties of cheese, whence the name. The process is a form of coagulation necrosis, beginning in the center of the tubercle. The cells lose their outline, their nuclei are no longer demonstrable by ordinary staining methods, and a confused granular mass results. Bacilli are, however, present. At times, on section, a quasi fibrillation appears in the caseated tubercle that is not to be mistaken for a true fibrous matrix. It may be the result of compression. Caseation is not limited to tubercle. Cellular inflammatory products and even cancer-cell masses may undergo the cheesy change.

Most frequently caseation is followed by *softening*. The precise conditions necessary for this are not known, though commonly, as soon as a

caseated mass reaches a certain size, it breaks down into a pyoid product which is not histologically pus, but consists of a number of fat drops, granular débris, and shriveled, formless cells. In the broken-down material the tubercle bacilli are exceedingly numerous, much more so than in the dry caseated tubercle. From this circumstance it is held by some that the caseation and subsequent softening are the effect of the bacilli, the action of which is compared to that of bacteria of decomposition. It seems much more reasonable to ascribe these degenerative changes to defective nourishment of the new formation. This view is sustained by the fact that softening does not take place until the tubercular mass acquires a certain size, commonly a half to one centimeter (0.2 to 0.4 inch) in diameter. The more rapid the formation the earlier does softening set in.

More rarely caseated tubercle becomes infiltrated with lime salts and undergoes *calcareous* change, by which a sort of healing is accomplished. The calcareous infiltration of tubercle is more especially prone to occur in lymphatic glands, but also happens rarely in the lungs.

Finally, a tubercle—and especially the miliary tubercle—may undergo a *fibroid change*, or sclerosis. Under these circumstances the new formation is converted into fibroid tissue. A certain more limited degree of cheesy metamorphosis takes place at the same time, but the product is a firm, tough nodule. This fibroid change is more prone to occur in tuberculosis of the peritoneum.

Secondary Inflammatory Processes.—So much for the change in tubercle itself. It is, however, capable of exciting *retroactive inflammation* in its own neighborhood. Thus, in the lungs a catarrhal pneumonia involving adjacent acini is often produced. In other instances an overgrowth of interstitial tissue ensues. Sometimes it is excessive and results in the so-called fibroid phthisis. More frequently this form of consumption is the result of a coincident irritation by another cause, such as the irritant particles encountered in such occupations as steel-grinding, stone-cutting, and mining. Associated with tubercular processes, especially in the lungs, is constantly found true suppuration, the result of mixed infection—whence the admixture of pus in the expectoration of pulmonary consumption. It is held by some, and apparently by Koch himself, that the tubercle bacillus is also capable of exciting suppuration in the absence of other pus-producing organisms.

II. ACUTE TUBERCULOSIS.

SYNONYMS.—*Diffuse General Tuberculosis; Acute Miliary Tuberculosis.*

Definition.—The simultaneous comparatively sudden development of miliary tubercles in different parts of the body as the result of an irruption of bacilli into the blood or lymph channels. It is the most emphatic expression of the infectious nature of tuberculosis. The infection is in almost every instance an auto-inoculation, of which the source is a nodule of softening tubercle in some part of the body.

In 300 cases of miliary tuberculosis examined by Buhl such a source was found in all but ten, while Simmonds in 100 cases found the caseating focus in every instance. The most common seat of such a nodule is the lungs, next a tubercular lymphatic gland, especially a tracheo-bronchial gland. After this there is less constancy, but tubercular joints, a tubercular pleurisy, tubercular peritonitis, and even a skin tuberculosis may be held

responsible. Such a nodule may break directly into a vein, furnishing an instance of true embolic infection.

Acute tuberculosis occurs most frequently in young persons between twelve and twenty years of age, but adults are not exempt. Any tissue or organ may be involved, but very seldom do we find all the organs of the body affected, though it is quite common to find lesions in more than two, as, for example, the lungs, the pleura, the membranes of the brain, and the peritoneum. The first three are favorite locations.

Clinical Varieties.—Three principal *clinical forms* of acute tuberculosis are recognized, one presenting signs of acute general infection without special localization, another exhibiting, in addition, easily recognizable pulmonary symptoms, and the third, cerebral and spinal symptoms.

I. GENERAL OR TYPHOID FORM OF ACUTE MILIARY TUBERCULOSIS.

Morbid Anatomy.—This is the anatomy of tuberculosis in the different organs and tissues of the body, and so far as not already described will be given when treating of the disease in these organs.

Symptoms.—The general or typhoid form of acute tuberculosis has long been recognized as resembling in a startlingly close manner the symptoms of typhoid fever, and many mistakes have been made in diagnosis because of this resemblance. Since the use of the clinical thermometer in diagnosis, however, such mistakes have been less frequent.

As in typhoid fever, a *prodrome* of several days, and even weeks, of ill-defined sickness often precedes the taking to bed. *Fever*, with its heightened temperature and frequent pulse, is present, as are also the dry tongue, hebetude, and delirium of typhoid. Yet fever is not always present, and afebrile cases are reported by Reinhold and Eichhorst. If differences are sought in the fever of the two diseases, it will be found that the pulse and respiration may be unduly frequent as compared with typhoid fever, but above all, the temperature will be found to differ in its course from that of typhoid fever. There is an absence of the characteristic "tidal wave" rise of temperature of typhoid. There is an evening rise and a morning fall; and an occasional inversion, with lower evening and higher morning temperature, takes place, which is held to be characteristic. The range is between 101° and 103° F. (38.3° and 39.4° C.), but may reach 104° or 105° F. (40° or 40.5° C.). The countenance is apt to be more dusky than in typhoid.

Excessive sweating is a symptom more characteristic of acute tuberculosis than of typhoid fever, and may result in sudamina, which also characterize the latter disease. *Herpes* is, however, often present, while it is almost a negatively pathognomonic sign of typhoid. These two symptoms—*i. e.*, sweating and herpes, together with the intermitting fever—constitute a resemblance to malarial fever. Waller and Eichhorst have found rose-colored spots on the abdomen and breast, but they are certainly infrequent, and they do not occur in crops as in typhoid fever. *Enlargement of the spleen* is often present and even *hemorrhage from the bowels* has been noted. Small *albuminuria* is a frequent symptom, not due, as might be expected, to a tubercular involvement of the kidney, but to the fever process.

Repeated examinations of the lungs fail to discover physical signs indicating disease of these organs, and thus the conclusion that there is no lung involvement is apparently confirmed. Later, however, pulmonary symptoms may set in, also meningeal symptoms, the duration of which may lead to a suspicion that the disease is not typhoid fever.

In view of the general possibilities of acute miliary tuberculosis, there may be *pleural* or *pericardial friction* and other symptoms of pericarditis and pleurisy, as well as those of *peritonitis* and *meningitis*.

Tuberculosis of the choroid coat of the eye has been frequently met in acute miliary tuberculosis, more particularly in cases where there has been the widest dissemination.

Notwithstanding the difficulties that attend the investigation, the instances in which tubercle bacilli have been found in the blood have been so numerous that in doubtful cases it should be examined. Rutimeyer suggests that the blood be taken for this purpose from the spleen by means of a hypodermic syringe, since it has been shown that the blood of this organ may be especially rich in bacilli. On the other hand, bacilli are rarely found in the sputum in acute general tuberculosis, even if there be involvement of the lungs, because in this form of tuberculosis the tubercles are situated not in the open air-passages so much as in the interstitial tissue of the lung and in the blood-vessel walls.

Diagnosis.—As stated, acute miliary tuberculosis resembles especially *typhoid fever*, but a carefully kept temperature chart will soon exhibit a difference in the two diseases from this point of view. If bacilli are found in the blood and tubercles on the choroid the question is settled at once. The duration of the disease, though short, is usually longer than that of typhoid fever, and before the clinical thermometer gave us its valuable information the first suggestion that something else than typhoid fever was present came about from noting an absence of the usual defervescence. The Widal reaction in typhoid fever and its absence in tuberculosis are valuable aids in the diagnosis.

It is well known that typhoid fever is characterized by a negative leukocytosis, that is, a diminution rather than an increase of leukocytes in the blood. Precise systematic studies of the blood in the typhoid form of acute miliary tuberculosis are wanting, but from such observations as have been made, it appears reasonable that in true, uncomplicated miliary tuberculosis, there is also wanting an increase in the colorless corpuscles of the blood over the normal. So soon, however, as there becomes associated with the tuberculosis any catarrhal or suppurative condition of the parts involved, a leukocytosis presents itself. It cannot, however, be said that leukocytosis is characteristic of true, miliary tuberculosis as contrasted with a diminished number of leukocytes characteristic of typhoid fever.

The resemblance to intermittent fever has been noted. Here, too, a close study of the temperature will soon show the difference, while a search for the hematozoon of malaria should be made. The failure of quinin to cure will settle the question against a malarial cause for the fever.

Prognosis.—The course is invariably toward an unfavorable issue. Scarcely ever less than four weeks in duration, it is often eight and even longer, although cases are reported to have terminated at the end of two weeks and even twelve days. Such must, however, be extremely rare. The relative shortness of duration, nevertheless, constitutes it one of the forms of *galloping* consumption. Acute miliary tuberculosis always terminates fatally sooner or later, although delusive improvements often raise hopes that are not realized.

Treatment.—Treatment for acute tuberculosis can only be symptomatic. To our present knowledge a cure has never been accomplished. Antipyretics may be used in moderate doses; three to five grains of antipyrin, antifebrin,

or phenacetin, the last probably the best, frequently repeated, abate the fever. Anodynes to quiet cough are also necessary. Supporting food and stimulants are indicated.

2. PULMONARY FORM OF ACUTE TUBERCULOSIS.

(a) *Miliary Tuberculosis Succeeding on Chronic Bronchitis, Chronic Tuberculosis, Whooping-Cough, Measles, etc.*

Symptoms.—This form succeeds in adults on chronic tuberculosis of the lung, on prolonged bronchitis, on whooping-cough or on measles in children. An irruption of miliary tuberculosis the result of infection takes place throughout the lung with or without bronchopneumonia. The tubercles may be scattered throughout the lung, distributed by the blood, and may be found in the walls of the vessels, or radially arranged around the primary focus. It is this event which gave rise to Niemeyer's dictum, "The greatest danger to most phthisical patients is the development of the tubercle." To the previous cough and physical signs are added higher fever, increased cough, and extreme dyspnea associated with marked cyanosis. The last symptom is very striking. The physical signs may not be altered; there may be sonorous and sibilant râles or there may be signs indicating deeper involvement of the lung, including small areas of impaired resonance, crepitant râles, and bronchial or bronchovesicular breathing (bronchopneumonic foci). On this account there may be rusty expectoration, rarely hemoptysis. The dull areas may alternate with areas of hyperresonance—hyperresonance due to relaxation (the Skodaic type)—or it may be due to localized emphysema. On the front of the chest, especially in some cases of miliary tuberculosis of the lungs, there may be unusual resonance. As the disease progresses moist râles become general all over the chest. Again there may be friction crepitation due to tubercular pleurisy.

Diagnosis.—The diagnosis is made by recalling the symptoms detailed. Choroidal tubercle should be looked for. Especially important are the disproportionate dyspnea and cyanosis associated with the signs of diffuse bronchitis. Leukocytosis is here present.

Prognosis and Treatment.—The disease is often rapidly fatal and treatment is of little avail toward cure. It must consist in efforts to make the patient comfortable, but as the diagnosis can perhaps never be made with absolute certainty the treatment to be detailed later for the cure of chronic tuberculosis should be carried out.

(b) *Pneumonic Phthisis—Bronchopneumonic Phthisis.*

This more unusual form of tubercular phthisis constitutes one variety of "galloping consumption," or *phthisis florida*. In it the tubercular infiltration is by a rapid peripheral invasion inciting to active inflammation. This is manifested as a bronchopneumonia, by which the air-vesicles and bronchioles are variously blocked with cheesy matter. The result is the dissemination through extensive areas of lung tissue of opaque, white foci one-fifth to one-half inch (5 to 12 mm.) in diameter. These areas are usually separated by others of a more or less congested but still crepitating tissue, contrasting strongly with the white of the tubercular bronchopneumonic foci. These tend to soften with varying rapidity, resulting sometimes in numerous

little abscess cavities throughout the lung. At other times the bronchopneumonic foci are more widely separated or may be limited to the apices. In more rare instances the condition may succeed on croupous pneumonia, forming continuous areas which may also extend throughout a lobe or entire lung. The process is truly pneumonic; the results resemble, indeed, more a lung in the second stage of croupous pneumonia. As in it, too, the lung is heavy and airless, sinking rapidly in water. There is, however, a greater tendency to disintegration than in croupous pneumonia, and cavities form rapidly in the apices and elsewhere.

There may also be enlargement of the bronchial glands in either of these forms, but more particularly in the first—the rapid peripheral extension.

Symptoms.—The *bronchopneumonic* form of consumption occurs most frequently in *children* as a sequel to measles or whooping-cough. In such seemingly ordinary cases of bronchitis, with *fever*, *obstinate cough*, and *shortness of breath*, physical examination will reveal submucous and subcrepitant râles throughout the chest with or without limited areas of consolidation. Tubercle bacilli and elastic tissue appear in the sputum. The fever continues and may become hectic, with sweats. The child emaciates rapidly, and death ensues in from three to eight weeks. Other cases originate more suddenly and with less apparent cause as cases of simple bronchial catarrh, which assume the graver picture described. Such children may inherit a predisposition to phthisis.

In *adults* the attack begins as an ordinary cold in a person with a predisposition to tuberculosis, though apparently healthy or run down with overwork. The *cough* is harassing, and soon becomes loose, *expectoration* mucopurulent. There are *high fever* and *rapid wasting*, and *hemorrhage* may set in to the surprise of everyone concerned. Then there may be a lull in the storm, but for a short time only. The symptoms, and especially the burning fever, wear out the patient. Bacilli and elastic tissue will now be found in the sputum and the diagnosis is settled. The patient may perish in three weeks. On the other hand, a reactive effort toward improvement may take place and after a time be followed again by decline and perhaps again by improvement, with the effect of prolonging the disease, but not of altering the termination. The physical signs are the same as in children, submucous and subcrepitant râles throughout the chest with or without limited areas of consolidation.

The pure *pneumonic* form succeeding what seemed to be croupous pneumonia is more an affection of adults. More rare, still, than the bronchopneumonic form, it may be also rapid in its course. It begins with a chill followed by fever, often after exposure to cold, with pain in the side, cough, dyspnea, mucous and rusty sputum, impairment of resonance, bronchial breathing, increased vocal fremitus—in fact, all the symptoms of a pneumonia of the whole or a part of a lung, which may be an upper or lower lobe. If the lower lobe, it is probably regarded as a pneumonia until the absence of the signs of resolution call attention to the fact that something unusual is going on. Later, softening and the signs of a cavity may present themselves at the apex, and bacilli and elastic tissue be found in the sputum. The case may last for three weeks or three months, or even pass over into a chronic phthisis.

Diagnosis.—In the bronchopneumonic form it is difficult to make the diagnosis early from simple bronchitis and bronchopneumonia. The temperature in phthisis is probably more irregular and higher. Where the disease lasts more than three weeks, the sputum should be examined carefully for

bacilli. The diagnosis in the pneumonic form can never be made in the beginning, because the symptoms of the first and second stages of this form are identical with those of the first and second stages of true pneumonia, and it is only when the type of the latter disease is departed from that phthisis can be suspected. The fever in true pneumonia should abate by the ninth day or twelfth day at latest, and if it continue after that time pneumonic phthisis should be suspected and the expectoration should be examined for bacilli.

Prognosis.—The prognosis is very unfavorable in this form of consumption, death being inevitable in from a few weeks to a few months. Rarely, patients live a year or longer.

Treatment.—Treatment of the acute stage is symptomatic. After the acute stage it is that of chronic phthisis.

3. MENINGEAL FORM OF ACUTE MILIARY TUBERCULOSIS. TUBERCULOUS MENINGITIS.

SYNONYMS.—*Tuberculous Leptomeningitis; Basilar Meningitis; Acute Hydrocephalus; Water on the Brain.*

Definition.—An acute inflammation of the pia mater due to an irruption of miliary tubercles on this membrane and on the blood-vessels proceeding from it, extending also at times to the corresponding membrane of the spinal cord.

Historical.—We are indebted to Dr. Robert Whytt for the first accurate information of this disease in his "Observation on Dropsy of the Brain," Edinburgh, 1768. In 1827 Guersant applied the term *granular meningitis* to this form of inflammation of the meninges, and in 1830 Pavoine showed the nature of the associated granules and called attention to their concurrence with tubercles in other parts of the body. In February, 1834, W. W. Gerhard, of Philadelphia, published in the "American Journal of the Medical Sciences" a paper on "Cerebral Affections of Children," based on a study of the disease made in the Children's Hospital in Paris. These studies included autopsies as well as clinical reports, and the descriptions of the lesions found in the former are so accurate that they can scarcely be improved upon. To Gerhard more than anyone else are we indebted for a proper location and classification of the disease.

Etiology.—I have said that the disease consists in essentially an irruption of miliary tubercles on the pia mater, with the resulting inflammatory product. To this end there must be somewhere in the body a tubercular focus whence the bacilli start. Tuberculous bones and joints may furnish such a focus, but it is most frequently located in the bronchial or mesenteric glands. Such focus cannot always be found, even when present. The bare possibility of a primary tubercular meningitis may, however, be admitted, in which event the cribriform plate of the ethmoid is the most likely route of bacilli inhaled from the external atmosphere through the nose to the brain. The disease is most common in children between the second and fifth years, though it is not very rare in adults long the subjects of tuberculosis.

Morbid Anatomy.—The pia mater at the base of the brain is the most frequent seat, whence the common term *basilar meningitis*. Particularly are the neighborhood of the optic chiasm, the Sylvian fissure, the interpeduncular space and pons varolii involved. In addition to the miliary tubercles are seen turbidity of the membrane increasing to opacity, the whole smeared over with fibrin and pus. The medulla oblongata and base of the cerebellum may be covered. More rarely the inflammation may extend to the lateral and convex surfaces of the brain. Especially do we find the adventitia-sheaths of the blood-vessels invaded by the tubercles, which are seen in bead-like rows

when the vessels are withdrawn from the substances of the brain. These vessels are better examined when spread on a dark background, with a low magnifying power. Sections of blood-vessels should be made also, because there may be tubercular infiltration of the intima, causing narrowing and obliteration of the vessel. The cerebral convolutions are softened to a slight depth by the invasion, the blood-vessels dragging a portion of the brain-substance when drawn out. Thus there is really a meningo-encephalitis.

The *lateral ventricles* contain a varying quantity of limpid or turbid fluid, a dram to several ounces, the ependyma is softened and swollen; the septum lucidum and fornix are disrupted. The convolutions may be flattened because of the pressure exerted between the dilated ventricles and unyielding cranium. More rarely there is a chronic process like that described, but slower in its course. As already mentioned, the pia mater of the cord may be involved, resulting in the same turbid picture.

Symptoms.—The symptoms of tubercular meningitis are varied and irregular in their course. At times, the beginning, at least to the superficial observer, is sudden. At others, there are many weeks of ill-health with ill-defined symptoms that go to make the child unhappy, restless, and an evident sufferer. In the course of such weeks the child's appetite is poor, its tongue coated, its bowels are constipated or the reverse, and it loses weight. The sudden events alluded to are a *convulsion*, *obstinate vomiting*, or *headache*. Such a child may have been convalescent from measles, whooping-cough, bronchitis, or other ills of childhood.

An attempt has been made with more or less success to divide the symptoms of the disease into stages, of which the first may be called *irritative*; the second, *that of subsiding irritation*; the third, *paralysis*. The symptoms most constant in the irritative stage are headache, fever, and vomiting, of which the latter may be first. As has been stated, convulsions may usher in the attack, and these convulsions may intermit and be separated by periods of some length. Sometimes an accident, as a fall, may be an exciting cause, and the first vomiting may be excited by a meal of food unsuited to the child's age. The three symptoms mentioned as more constant grow in severity, especially the headache, which becomes more or less incessant and intense, so that the child is never free from it. Yet there may be a lull in the pain as the result of treatment or other cause, followed by an acute exacerbation, which probably causes the peculiar short cry known as the "hydrocephalic cry." In other cases there is constant screaming, which points to the degree of suffering. The child rarely sleeps more than a few minutes at a time, unless under the influence of powerful anodynes. There is always *fever* in this stage, though it may not be very high, 103° F. (39.4° C.) being commonly the maximum. There is more or less delirium. The *pulse* is rapid, even rapid disproportionately to the temperature, while the *breathing rate* is little altered, furnishing a symptom of some diagnostic value. Evidences of nervous irritation may occur early, more commonly late in this stage. The convulsion has been alluded to. The pupils may be contracted or irregular, there may be strabismus, or twitching of the muscles of the face from involvement of the facial nerve.

In the *second stage* delirium yields to coma, though convulsions may continue. There may be localized rigidity of the muscles of one limb or of half the body. The head may be retracted. Headache is not complained of, though the child still may occasionally cry out. The pupils are dilated or irregular and squint is more marked from oculo-motor or third-nerve paraly-

sis; the bowels are constipated; the abdomen is retracted—scaphoid. The temperature tends to be lower, but is variable. There is often a patchy redness of the skin and *tâche cérébrale* may be brought out by drawing the finger-nail across the skin.

In the *third period*, or *stage of paralysis*, the stupor increases and may be profound. Convulsions, however, still occur. They may be localized in a group of muscles or those of one limb, or the convulsion may be unilateral. On the other hand, there may be absolute paralysis of the oculo-motor nerves, and even hemiplegia. As a result of the former the pupils are dilated, the eyelids partially closed, and the eye turned upward. Hemiplegia is more apt to occur when the fissure of Sylvius is invaded, when, too, there may be aphasia. Optic neuritis is sometimes present in this stage, usually occurring late, due to invasion of the optic nerve within the skull. The facial nerve may be involved in basilar cases, producing slight facial paralysis; so may the fifth, producing anesthesia, and atrophic changes in the cornea if the Gasserian ganglion be involved. Hyperesthesia of the special senses may also be present, though this is rather a symptom of the first stage. Toward the end a typhoid state may supervene, characterized by dry tongue, muttering delirium, and involuntary discharge of urine and feces. The temperature at this stage may be subnormal, falling as low as 93° F. (33.9° C.). On the other hand, the temperature sometimes rises just before death to 106° F. (41.1° C.) or more. The entire duration of the disease is from two to three weeks. The blood examination fails to find a characteristic leukocytosis.

Diagnosis.—In the diagnosis we have first to recognize the presence of a meningitis, and, second, to separate the tubercular meningitis from meningitis due to other causes. The former is commonly easy, yet mistakes are often made because so many of the head symptoms are simulated by head symptoms in dyscrasic conditions, of which cholera infantum is a type, while retraction of the head may result from rheumatism of the muscles of the back of the neck; but optic neuritis and paralytic symptoms are confined to meningitis. The presence of tuberculosis elsewhere strengthens other signs. The other forms of meningitis that may give similar symptoms are meningitis due to internal ear disease, traumatic meningitis due to blows and injuries, and syphilitic meningitis. In meningitis due to ear disease the history of the case should prevent a mistake. Traumatic meningitis, especially with abscess, might simulate the symptoms described, but here, too, the history of the accident would be helpful, but in absence of a knowledge of the cause there might be confusion. Syphilitic meningitis is usually chronic, rarely acute, although it affects the base of the brain; also, the lesion is more apt to be limited in area and confined to one side. Basal headache and signs pointing to localization are present. Often the history does not help us because the patient denies the existence of the specific cause. Syphilitic disease involves the convexity more frequently than does tubercular, causing the symptoms of cortical lesions, including focal convulsions. The diagnosis is most conclusively established if tubercles be detected in the choroid.

Prognosis.—The prognosis of tuberculous meningitis well established is invariably fatal. On the other hand, the chances of error in diagnosis are so many that it is not wise to be too confident. It has happened to me more than once to have had cases in children recover where I had thought the disease present, but where the ultimate result proved the diagnosis erroneous.

Treatment.—Curative treatment is, therefore, futile, but for the same reason should be persevered in. The cases whose recovery has surprised me

have invariably been those in which I used cod-liver oil inunctions. These should, therefore, be persisted in. In addition to this all other supporting measures possible should be used with such treatment of symptoms as will secure the least suffering to the little patient.

III. CHRONIC TUBERCULOSIS.

I. PULMONARY TUBERCULOSIS.

SYNONYMS.—*Phthisis pulmonalis*; *Pulmonary Consumption*; *Consumption of the Lungs*.

The Greek term *φθισις* is an admirable word, meaning literally wasting, which is almost, if not quite, the most characteristic symptom of the disease known technically as *phthisis pulmonalis*.

Definition.—Pulmonary tuberculosis is an infectious disease due to the lodgment and proliferation of the tubercle bacillus in the lung substance.

Etiology.—The dependence of tubercular consumption on the tubercle bacillus and its various favoring elements has been fully considered under the head of General Tuberculosis, page 238. There are two possible routes of invasion of the lungs, one by the air-passages,—inhalation tuberculosis,—the other by the blood. The former is by far the most common for ordinary forms of consumption, while the latter produces usually miliary tuberculosis.

Morbid Anatomy.—*Inhalation Tuberculosis.*—The bacillus, notwithstanding its probable detention at various points in its journey, rarely obtains a fruitful soil until it reaches the ultimate ramifications of a bronchus or its termination in the alveolar passages, infundibula, and air-vesicles. It is in the septa forming these that it locates itself by preference, multiplies, and excites secondary inflammatory processes, the sum of which constitutes the *tubercular nodule*.

A correct understanding of what is to follow may be facilitated by a review of the drawing on p. 253, showing a single lung lobule 1.5 cm. long and 1 cm. broad, magnified ten times. The principal bronchus is seen entering the lobule and dividing into seven smaller bronchioles, and each of these into two still smaller ones. These smaller bronchioles open directly into a group of from three to five branching alveolar passages, with their infundibula beset with air-vesicles. These form the equivalent of an acinus in a racemose gland, and may be termed *lung acini*, a more constant unit of lung structure, as Rindfleisch truly says, than the lobule, at least as far as size is concerned, since as few as two of these may unite to form a lobule, or as many as 20 to 30. The figure in the text is made up of 14. In pathological processes other than tuberculosis, the lobule is the more important element, since each is determined by the distribution of the blood-vessels and interstitial connective tissue. Emboli, infarcts, and abscesses therefore light upon the border of the *lobules*, while the miliary tubercle is found between the bronchioles and within the *alveolar septa*, where the bacillus secures lodgment and the tubercle its growth. This favorite position may be seen by making a section across one of the smaller bronchioles after it passes into the acinus, when we will meet the circular edge of a bronchiole and an entire system of partitions between three and five alveolar passages.

Under the irritating influence of the bacillus, these septa undergo cellular infiltration, which results in their thickening and encroachment upon the

lumina of the air-passages. By this process is produced a little granulation that corresponds at first in size to an acinus, and enlarged by the implication of other acini until a lobule is finally involved, producing an irregularly rounded or oval body assuming somewhat the shape of a lobule, ranging in diameter from one millimeter to six millimeters (1-25 to 1-4 inch).—the *tubercle granulum*. On section such a granule is found perforated by one or more minute openings or slits corresponding to the air-passages, one for each of the roundish subdivisions which make up the nodule. In vertical section the appearance is more definite, having a central stem with branches. The area is whitish-yellow in color, surrounded by a ring of hyperemic tissue. The microscope shows the periphery of the bronchiole or air-passage infiltrated with concentric layers, of which the external is made up of small

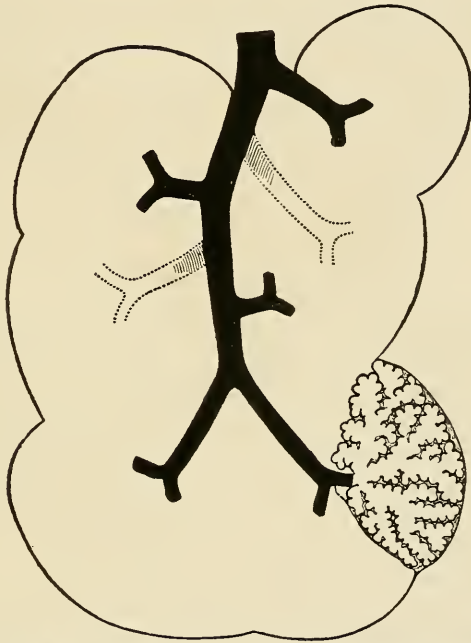

Fig. 22.—Lobule of Lung, Showing Acini and Alveolar Passages—(after Rindfleisch).

lymphoid, the middle of large epithelioid cells, and within this again a third zone in which no cells are differentiable, these having lost their contour and become fused into a homogeneous mass—in a word, having become caseous. The lumen of the tube itself is plugged with cheesy matter. The blood-vessels stop short at the edge of the tubercle, as it is thoroughly avascular.

By suitable staining methods, tubercle bacilli may be demonstrated among the cells of the tubercle granule in moderate numbers at its periphery, but not in the cheesy center, where they do not seem to thrive until softening takes place, when they are found in great numbers.

Thus begin most cases of pulmonary phthisis as a localized tuberculosis of the smallest air-passages at the apex of one of the lungs. The apices are attacked first, because here the unfolding of the lungs, in the act of breathing, is more limited, the blood moves less freely and tends rather to stagnate—conditions which favor the retention of secretion, favor the lodgment, and encourage the growth of the bacillus.

On the other hand, the view so long entertained that the left apex is more frequently affected than the right seems to be erroneous in the light of modern studies. Thus, William Osler out of 413 cases found the right apex involved in 172; the left, in 130; both, in 111. Pension examinations furnish an opportunity for obtaining information on this subject, and my friend, Theodore G. Davis, of Bridgeton, N. J., took occasion, as examiner in a pension board, to note the cases of tubercular phthisis which passed before his board, with the following results: Out of 897 males, whose ages ranged from forty-five to seventy-one years, 94, or about 10 1-2 per cent., had pulmonary tuberculosis, more or less pronounced. Of these, 39 were markedly worse on the right side and 29 on the left; both sides were affected in 26—proportions very like those of Osler.

From this usual starting point the disease spreads with varying rapidity to other parts of the lung. Two principal varieties, however, result, based upon the rapidity of the spread of the disease. The first includes the ordinary chronic form of consumption, or *chronic ulcerative phthisis*, and an allied slow form characterized by a special involvement of the connective tissue, known as *fibroid phthisis*; the second is *pneumonic phthisis*, one of the forms of galloping consumption, which has already been considered.

(a) *Chronic Ulcerative Phthisis.*

SYNONYM.—*Slow Consumption.*

Morbid Anatomy.—This most usual form of consumption, beginning with the tubercle granulum and associated with more or less catarrh of the apex, extends thence slowly downward. The deposit in the beginning is not actually in the very apex, but a little below it, and usually the first point at which physical signs are found is on the middle of the clavicle or just below it. Sometimes, however, the extension is rather backward, so that the physical signs are first manifested in the supra-spinous fossa, whence the importance of always insisting on the posterior examination.

From this initial focus, usually toward the anterior face of the lung, the disease extends more or less throughout the lobe, or it may pass to another lobe. If the disease be on the right side, from the upper it may extend to the middle lobe and thence into the lower lobe about an inch below its apex, corresponding also to a point on the surface opposite the fifth dorsal spine. On the left side, the extension is directly from the upper to the lower lobe. From its previous focus the tubercular infiltrate travels centripetally along the bronchi from smaller to larger as a tuberculous peribronchitis. As E. Rindfleisch aptly expresses it: "The white berries acquire a stalk of the same nature and color. The stalks unite with each other and thus form a radiating or rudely stellate focus of larger extent." These stalks are bronchioles the walls of which are infiltrated with tubercle. Larger and larger branches become implicated with the intermediate parenchyma, but usually it does not extend beyond the cartilage-ringed bronchi of the second order, forming tubercular masses of corresponding size.

The infiltration is not limited to peribronchial tissue. It extends also inward toward the lumen of the tube, invading the submucous tissue, where it may be seen as whitish or cloudy patches on slitting up the bronchi and washing off the adherent muco-pus. Thus uncovered, the mucous membrane is found also red and inflamed, contrasting strongly with the whitish patches

referred to. As we penetrate deeper, these enlarge and intrude upon the lumen of the tube, while the hyperemic areas grow smaller. Such intrusion becomes finally complete occupation, associated, sooner or later, with an excoriation or rupture of the mucous membrane. This is the beginning of ulceration, which assumes an important place in facilitating subsequent destructive process, and is the foundation of the term adopted for this form of phthisis, *chronic ulcerative phthisis*.

The pathological processes referred to, and the destructive effects of which they are the cause, give to the lung in a state of chronic phthisis a varied picture that is not always found in a single case, nor, indeed, would the lesions of two or more cases always cover this picture. They include the following:

1. The *caseous tubercular masses*, formerly called crude tubercle. They embrace single or compound peribronchial foci perforated by the central bronchiole, itself plugged with cheesy matter. Thus constituted they form grayish-yellow masses from a couple of millimeters to four or five centimeters (1-12 to 2 inches) in diameter. They have the composition already described. Though usually massed toward the apices of the lung, they may also be disseminated through the remainder of the organ, and around them there may also be found scattered true miliary tubercles.

2. The second anatomical feature of the phthisical lung is the *cavity*. As soon as a tuberculous area reaches a certain size, the tendency to break down is increased, though such tendency does not depend altogether on extent. The bronchial wall, weakened by the tubercular infiltration and the ulceration referred to, is the initial invitation. The wall yields to the pressure which it formerly easily resisted—the inspiratory and expiratory strain incident to coughing,—the bronchus dilates, the gap of the ulcer widens, and the texture of the bronchus gradually yields. The free access of air to the already necrotic caseous matter causes it to soften, break down, and a cavity results. Small foci unite with others and thus larger cavities form, occupying the greater part of a lobe, or even a whole lung in very rare instances.

Large cavities have usually smooth walls and are lined by the so-called pyogenic membrane, into which, however, often protrude blood-vessels of large size, as thick as a crow-quill, and exhibiting also at times aneurysmal dilatations. Rarely such vessels pass directly across a cavity, and when eroded they may give rise to fatal hemorrhage toward the end of a case of chronic phthisis. On the other hand, these vessels may also become thoroughly occluded by an obliterating endarteritis. The surface of these smooth-walled cavities is constantly producing pus, while muco-pus is being added by communicating bronchi. Such cavities may be more or less completely emptied by expectoration. They are also surrounded by a consolidated lung tissue, which gives a dull percussion note and thus often prevents the tympany natural to a cavity. Small cavities have rough and ragged walls, from which there is constant breaking down, adding elastic tissue, pus, granular débris, and bacilli to the matter expectorated. There may be a number of these small cavities, and if under the pleura one may rupture into the pleural sac, producing pneumo-thorax.

Other cavities form by the softening of the center of a caseous area. Others still may be purely bronchiectatic, being limited by bronchial walls. It is more particularly the bronchi of medium size that are thus involved, weakened also by tubercular infiltration. The form of dilatation may be cylin-

drical or globular. The small tubes especially may be the seat of cylindrical dilatation.

3. *Pleurisy* is constantly associated with tubercular phthisis. It is found in four forms:

(a) As an adhesive pleurisy in the immediate neighborhood of tubercular infiltration, causing a collateral hyperemia and inflammation of the pleura.

(b) There may be perforation from a cavity into the pleura, exciting a purulent pleurisy and a pyopneumothorax.

(c) A pleurisy may be lighted up by cold in a favorable focus of collateral hyperemia.

(d) Finally, the pleura may be the seat of a tubercular pleurisy, resulting in a thickened membrane, which may be limited or may encase the whole lung and cement the lobes in a continuous inseparable mass.

4. *Pulmonary concretions* are also found in the phthisical lung, usually about half as large as a pea, smooth or lobulated. They represent calcareous infiltration of alveoli* of the lung, filled with tubercular bronchopneumonic products. They are a medium of one form of healing of tuberculosis. Those retained in the lung are commonly surrounded by a ring of hyperplastic connective tissue. At times they are expectorated, being released by a sequestering suppuration into an adjacent bronchus, whence they are brought up by coughing. Sometimes a good many are coughed up. They are something different from *bronchial calculi*, which are always smooth, spherical, or elliptical, and are found in small bronchitic cavities.

5. Other evidences of *attempts at healing* seen in the phthisical lungs are of the nature of reactive inflammation. They may occur:

(a) In the initial stage as the result of treatment and favorable hygienic surroundings, when the initial granule is replaced by a cicatricial-like puckering of fibrous tissue or a hard cartilaginous mass of connective tissue.

(b) There may be a sequestration or encapsulation of a cheesy nodule, which may or may not undergo calcareous infiltration.

(c) Even a cavity of moderate size may heal, in which event, the cavity being cleared out, its walls unite by adhesive inflammation and thus a band of cicatricial tissue takes the place of the cavity. Larger cavities may be reduced in size by a contraction of the cicatricial tissue surrounding them, or several small cavities may be thus surrounded. Quite small cavities surrounded by connective tissue and communicating with a bronchus were called *cicatrices fistuleuses* by Laennec.

6. The neighborhood of a tubercular infiltration is often the seat of a pneumonia which may be simply reactive or due to the irritative effect of the bacillus—*i. e.*, a *tubercular bronchopneumonia*. The area is hyperemic, hard, consolidated, and the air-vesicles filled with exfoliated epithelium. The latter may exhibit various stages of fatty degeneration. It may be complete when an appearance indistinguishable from that of tubercular infiltration is present. In fact, it is tubercular infiltration plus catarrhal pneumonia.

7. When a subject dies of tubercular phthisis, *other organs* should be searched for *tubercles*. Tuberculosis of the larynx is common and is not infrequently associated with destruction of the cords and epiglottis. The bronchial glands are usually involved, swollen, inflamed, or tubercular, and when tubercular may become caseous and sometimes calcareous. Other glands are also affected, such as the cervical, mediastinal, and post-peritoneal.

* If macerated in hydrochloric acid the lime salts can be dissolved out, and the actual elastic tissue framework of an alveolus, with its infundibula and attached air-vessels, be left.

It is now recognized that the so-called "scrofula" of the neck is a tuberculosis of lymphatic glands. After the bronchial glands the organs most affected are the intestine; next, the spleen, kidneys, and brain in nearly equal proportion; then the liver and the pericardium.

8. The only remaining morbid states which may be considered as having any essential relation to tubercular consumption are the *amyloid* and *fatty infiltration*. The former is found affecting the kidneys, liver, spleen, and mucous membrane of the intestines; the latter, especially, the liver and kidney.

Symptoms.—The onset of tubercular consumption is by no means uniform. Notwithstanding the fact that its insidious nature is well recognized, its initial stadium is often overlooked. The victim is scarcely appreciably ill. Yet he may lose flesh and strength continuously. He may even say that he has no cough, while close questioning will ascertain that he has had a *slight hacking cough* for some time, worse in the morning. Soon the symptoms are plainer, there is *evident wasting*, an *intermittent fever*, a *bright eye*, and the *cough with expectoration* is a conspicuous symptom. Yet during all this the patient is cheerful and denies that there is much the matter with him.

In another instance an individual is "subject to cold"; he takes cold repeatedly, and each attack, while passing away, yields more stubbornly than the previous one, and finally one comes that persists. There is *daily fever* which abates to return again, emaciation is evident, and the bright eye and burning cheeks and *night-sweats* again attest the arrival of the dread disease.

Another case may begin with *hoarseness*, due probably to tubercular laryngitis, not infrequently the initial symptom.

Again, after a stubborn attack of bronchitis in a person previously healthy a *hemorrhage of the lungs* unexpectedly makes its appearance, or such a hemorrhage may set in without previous warning, although, again, careful inquiry may find that cough has been present for some time. The patient has, perhaps, previously been overworked, or lived under unfavorable hygienic surroundings, or may possess a hereditary tendency.

In still another instance a patient may consult the physician without suspecting that he is very ill, and the signs of advanced disease of the apices will be found present, and there may be but a few more months of life remaining to the unsuspecting victim.

A certain number of cases of consumption begin as *tubercular pleurisy*, which invades the lung by contiguity or by blood infection. One of the most convincing facts in favor of the infectious theory, which seemed established prior to the discovery of the bacillus, was the frequent occurrence of pleurisy as a forerunner of phthisis. It was held that the caseous product of the pleurisy furnished the infectious virus, which, entering the blood, caused tubercle formations in various parts of the body. Thus, one-third of the 90 cases of pleurisy followed up by Bowditch terminated in phthisis.

Inveterate dyspepsia is associated with many cases and is as often a predisposing cause as a symptom. A great loss of appetite and indisposition to take food are often symptomatic, and their presence does much to diminish the efficiency of remedies and nutriments so essential to successfully combat the disease.

Physical Signs.—Given the suspicion of the existence of tubercular consumption from the presence of the above symptoms, whatever others may be superadded, or whatever modification may occur in them, the diagnosis is

completed by a physical examination. The physical signs, therefore, will be next studied. While it is not always easy to separate the clinical history of a case of consumption into three sets of symptoms corresponding to the three separate stages in the morbid anatomy, the physical signs corresponding with these stages are tolerably definite. They are:

1. The incipient stage, or beginning deposit.
2. Stage of complete consolidation.
3. Stage of softening and cavity formation.

1. *Inspection*, in the *incipient stage*, is as often negative as not. A slightly diminished expansion in the infraclavicular space, as compared with the opposite side, may be present, and more rarely a slight flattening of the same region. The clavicle becomes correspondingly conspicuous. The body may continue well nourished or slightly emaciated, or the heart-beat in the normal position may be somewhat accelerated, while the respirations are likely to be more frequent than in health.

Palpation may recognize increased vocal fremitus in the same situation, although not always, while the physiological difference in favor of the right side is to be remembered. *Percussion* in this stage gives slightly higher pitch and impairment of resonance, which may be noted above, on, or below the clavicle. Dullness may sometimes be brought out by directing the patient to hold his mouth open during percussion or to hold his breath at expiration.

To *auscultation* above or below the clavicle, we have the first evidence of abnormality in a prolongation of the expiratory murmur and harshness in the inspiratory sound—in a word, in bronchovesicular breathing. Theoretically, this should be preceded by a diminished intensity in the inspiratory sound, owing to the interference of the newly-deposited tubercles with the entrance of air into the air-vesicles, but practically such diminished intensity is rarely encountered, and even if present is not of distinctive significance.

Increased vocal resonance is a constant accompaniment of these modifications in the normal breathing-sounds, but it, as well as the vocal fremitus, may be masked by a pleuritic thickening, and the physiological difference so often referred to must be remembered. J. M. Da Costa also calls attention to the fact that in a certain number of cases, at this stage, there is a blowing sound in the subclavian or pulmonary artery, and that a murmur is sometimes present in these vessels before any other physical sign is noted. There are frequently concurrent with these signs those of a bronchitis more or less acute.

2. In the *second stage* the changes discoverable by *inspection* are more easily recognized. There is evident loss of flesh, depression of surface, and impaired range of respiratory movement. The hectic flush is intermittingly present. *Palpation* may even discover an increased warmth of skin. The increased vocal fremitus is now plainly recognized unless obscured by a thickened pleural membrane. Dullness on *percussion* is positive and easily elicited.

To *auscultation* there is increased vocal resonance. The bronchial factor in the breathing now becomes conspicuous, showing itself by the harshness and relative shortening of the inspiratory element, with the decidedly prolonged and blowing expiration; also a gradual diminution of the vesicular factor, until the latter disappears entirely, when we have the typical bronchial breathing of extended areas of tubercular infiltration. This sign will now be found in the suprascapular fossa posteriorly as well as anteriorly. The conduction of the normal heart sounds to the area of infiltration, if at

either apex, is a very frequent and significant sign. The high degree of vocal resonance known as bronchophony is also superadded as a valuable confirmation of the presence of complete consolidation. The auscultation signs of a concurrent bronchitis may also be present in this and in the next stage.

3. In the *third stage* the information furnished by *inspection* is still more positive. Emaciation is marked, breathing and the pulse are rapid, and the face is often flushed. There is flattening over the affected area, and the excursion of respiratory movement is still more limited. In this stage the superficial veins over the involved area may be prominent, partly from emaciation and partly from obstructed circulation. There may be visible pulsation in the second, third, and fourth interspaces to the left of the sternum because of the retraction of the lung, while the heart may even be drawn up if this retraction be of the left upper lobe. This is seen more particularly in the variety known as fibroid phthisis. To *palpation* the vocal fremitus is still more marked, and even remains distinct over cavities, because of the consolidation around them, unless there be some obstruction to the entrance of air into the bronchus leading to the involved area. Rhonchal fremitus may be added if adventitious sounds be present. The skin is hot and dry, unless succeeding one of the sweats that characterize this stage, when it may be moist and clammy.

Dullness on *percussion* is always to be found in the third stage, but to it is often added some one of the varieties of tympanitic note—viz., pure tympany, the “cracked-pot” sound, or amphoric resonance, due to cavities. These require sufficient size and superficial situation on the part of the cavity. On the other hand, resonance may even be normal over a cavity some distance from the surface, especially if the percussion be lightly made, while the consolidated tissue which almost invariably surrounds a cavity often permits only a dull sound to be elicited. Wintrich’s change of note should be sought—a change of note produced during percussion over a cavity on opening and closing the mouth, the pitch being higher when the mouth is open.

Auscultation in this stage may continue to recognize the bronchial breathing of the second, but to it are superadded first small bubbling sounds or subcrepitant râles indicating liquefaction; later, may be added the distinctive signs of a cavity. These signs are cavernous breathing, cavernous voice, pectoriloquy, either whispering or loud speaking, amphoric breathing, and amphoric voice. To these are often added the large bubbling sounds known as gurgling, caused by the air bubbling through fluid in a cavity. Metallic *tinkling* may be added to these phenomena, caused by the bursting of bubbles in a cavity with amphoric conditions.

“Cavernous breathing,” strictly speaking, is any modification of the normal breathing sounds due to the air passing in and out of a cavity. When high pitched it becomes tubal or amphoric. The amphoric sound is supposed to occur in cavities with firm walls that best secure the “echoing,” which is the condition of amphoric breathing and amphoric percussion. Over more yielding walls the breathing is lower pitched, and to this the term “cavernous” is especially applied.

Special Symptoms.—The *cough* of consumption varies greatly. It is at first very slight, and may continue so even in advanced stages. As a rule, however, it grows in severity with the progress of the disease. It is caused by the irritation of intercurrent bronchitis or bronchopneumonia or the accumulated contents of cavities. When a cavity becomes more or less filled with secretion it must be emptied, and a spell of coughing comes on

and continues until the cavity is cleared out, whence the paroxysmal character so often assumed by the cough when this stage is reached.

The *expectoration* of tuberculosis varies with the stage of the disease. At first scanty, and in no way characteristic, it grows more copious and becomes puriform as the disease progresses. A more or less circular shape is finally assumed, which is somewhat distinctive, and is called "nummular," from its resemblance to a coin. The quantity of expectoration varies greatly, from 1-2 ounce (15 c. c.) to 1-2 pint (250 c. c.) in the twenty-four hours. It generally has a sweetish, unpleasant odor, but is rarely offensive. It is sometimes tinged with blood, and may contain Charcot's crystals (p. 265).

Minutely, the expectoration is made up chiefly of pus-corpuscles, among which may, however, be found epithelial cells from the mouth and lung alveoli, elastic tissue from the air-vesicles, more rarely from the bronchial tubes or blood-vessels, oil drops, particles of food, generally innumerable tubercle bacilli, and at times blood-discs. The elastic tissue is most easily demonstrated by boiling the sputum in a test-tube with an excess of solution of potash or soda, the effect of which is to thin the sputum and permit the elastic tissue to fall to the bottom of the tube; whence it is easily carried by the pipette to the glass slide and recognized under the microscope by its wreath-like or circular shape, if derived from the air-vesicles. Care must be taken to eliminate fibers of elastic tissue that may be derived from food. To this end the mouth should be carefully rinsed before collecting sputum for examination, and it is further to be remembered that particles of food containing such tissue may remain in the mouth for two or three days. The elastic tissue from the bronchi occurs in the shape of elongated or reticular fibers. That from blood-vessels is similar; more rarely it is fenestrated membrane. The alveolar epithelial cells are round and oval, mononucleated, highly granular, nearly twice the diameter of a pus-corpuscle.

The bacilli, which are an unfailing sign of tuberculosis, are demonstrable only by special staining methods, of which that by carbol fuchsin, with or without Gabbet's counter-stain of methyl-blue (see p. 238), is recommended.

One of the most unpleasant consequences of the cough is the *vomiting* which it induces, more especially in the last stages of the disease. It is not unusual to throw up a meal immediately after it is taken as the result of a paroxysm of coughing. Such vomiting is probably a reflex act, excited by irritation of the pharynx in coughing. Fortunate is the patient who can immediately thereafter take another meal, since this meal is generally retained, because the accumulated muco-pus which caused the coughing spell is also thrown up with the food in the first act of vomiting, and the cough ceases for a while.

Pain is not inherent to tuberculosis—that is, the seat of a tubercular infiltration is not usually a seat of pain. Pain is, however, a frequent secondary symptom. It is most severe as the result of a concurrent pleurisy, when it is usually sharp and cutting at the site of the pleurisy. Pain also results from inveterate cough. Such pain is usually in the lower part of the chest and is mainly caused, I believe, by the motion to which this part of the thorax and the diaphragm are subjected in the act of coughing.

Fever is a symptom of all stages of pulmonary consumption. At the onset there may be fever of an irritative kind, due to the deposition of the tubercle and to inflammation. This is a fever of a continued type with

Fig. 23.—Chart Showing Extreme Range of Temperature in Tubercular Phthisis.

slight evening increments, often overlooked, until it becomes associated with hectic fever, which is a septic fever occurring during softening and cavity formation. *Hectic* fever is one of the most interesting symptoms of consumption, adding often a picturesqueness that increases the sadness of the situation. Coming on usually toward the end of the day, the maximum point is reached at no fixed hour, but generally occurs between 2 and 6 P. M., though it may be as late as 10 P. M. The minimum, usually noted

Fig. 24.—Temperature Chart of a Case of Tubercular Consumption without Fever, long under treatment at the Hospital of the University of Pennsylvania.

between 2 A. M. and 6 A. M., may occur as late as 12 noon. Hence, frequent observations of temperature should be made during the day and night, two in twenty-four hours being inadequate. Once in four hours is not infrequently desirable, and where careful study is desired, once in two hours may be necessary. The chart (Fig. 23), on page 261, shows extreme range of temperature in hectic fever.

There is, however, no greater mistake than to suppose that every case of consumption must have fever throughout. It probably always has fever in the beginning—the fever of onset; but with the disease once established it frequently happens that there is no fever in any part of the twenty-four hours. Appended is a chart of such a case (Fig. 24).

In the course of a case of consumption it constantly happens that periods occur of various duration, from one to seven days, in which the fever is higher than usual with moderate remissions, say of one degree, and attended with increased localized pain. These are explained by the occurrence of new patches of bronchopneumonia, which may be either simple or tubercular.

The fever of hectic is generally followed by *sweating*, sometimes limited to the head or the neck. The occurrence of sweats in the night, or rather toward morning, has given rise to the term “night-sweat.” They are not, however, confined to the night, but may occur at any time, especially during sleep.

The *pulse* is always frequent in tubercular consumption, and gradually grows feebler as the disease progresses.

Hemorrhage from the lungs is a symptom everywhere associated with the idea of consumption. There are two periods in which it occurs—one

early and one late. The early hemorrhages are usually moderate and are due to the rupture of blood-vessels weakened by tubercular infiltration. They are sometimes the very first announcement of the presence of the disease, at others they are a means of relief to a certain feeling of oppression in the chest which precedes them. Their greatest danger is production of an insufflation pneumonia by the inspiration of small particles of clot that act as irritants. When the hemorrhages are small the blood is often admixed with mucus, constituting the true hemoptysis. In such cases the blood probably comes from the mucous membrane of the bronchial tubes. The hemorrhages late in the disease are commonly large, sometimes enough to cause immediate death. The amount of blood lost in such a fatal case has reached four pounds (1.8 kilos). Yet enormous hemorrhages are sometimes survived. They are due to ulceration into a large blood-vessel, often one of those described as traversing the wall of a cavity or bridging it from side to side.

Diarrhea is a frequent symptom late in the disease. It is commonly due to tuberculosis of the bowel and is often exceedingly obstinate. Not every diarrhea, however, in tuberculosis is tubercular.

The *club-finger* was noted by Hippocrates, and has long been associated with consumption—though not peculiar to it. It is a condition found in other chronic diseases, as emphysema, chronic bronchitis, chronic cardiac disease, and aneurysm. The end of the finger is bulbous, quite like a club, and the nail curves over the end. It may involve some of the fingers only.

Tuberculous meningitis may be added toward the close of the disease. In it there is extension of tuberculosis to the membranes of the brain, producing symptoms such as *pain in the head, delirium, acute mania, vomiting, fever,* and finally *convulsions* and *coma*. The symptoms vary a good deal with the seat of the involvement, and have been considered in detail when treating of tubercular meningitis. If the inflammation is in the fissure of Sylvius, there may be aphasia and even hemiplegia; if at the base, retraction of the head and palsies of the cranial nerves from pressure, also optic neuritis; if on the convexity, delirium is more decided, and there may be local convulsions with hemiplegic weakness. Ventricular effusion—acute hydrocephalus—adds little to the specialization of symptoms. There may be co-involvement of the membranes of the brain and spinal cord, producing symptoms of cerebrospinal meningitis.

The relation of pulmonary consumption to *cardiac disease* has always been an interesting one. It is commonly thought that affections of the heart and lungs are never concurrent. Occasionally such concurrence is observed, but whether such relation is any but an accidental one is doubtful. Osler reports 12 instances of endocarditis in 216 autopsies on cases of consumption. The rarity of lung tuberculosis succeeding chronic valvular heart disease must still be admitted. It has been ascribed to hypertrophy of the unstriped muscular structure about the smaller bronchioles and their acinous terminations, which keeps the alveoli evacuated of such secretions as favor the development of phthisis.

Chronic nephritis and *amyloid kidney* are frequent complications of chronic phthisis. From these causes *albuminuria* may result. There may be simple febrile albuminuria. Or albuminuria may be due to pus, if there is tuberculosis of the bladder or kidney. Tubercle bacilli should be sought for in purulent urine.

The *liver* is often enlarged from fatty infiltration.

Diagnosis.—The diagnosis of chronic tubercular consumption may be

difficult in the early stages, but later, when the physical signs have developed, it is easy. Even in the early stages the finding of the bacillus removes all doubt. Occasionally, however, the sputum is very scanty and difficult to get. If such an examination is not possible, or furnishes negative results, some days may elapse before a positive diagnosis is obtained. For the physical signs in the early stages cannot always be relied on, while there occur cases in which, even months after bacilli have been found in the sputum, the physical signs are confusing and inconclusive. Due regard must be paid to the fact that in health the expiratory sound below the right clavicle is longer and rougher than in a corresponding position on the opposite side, while the percussion note may also be somewhat higher pitched. The presence of fever more or less constant, the bright eye, and crimson flush in the cheek, with or without emaciation, should excite suspicion and lead to careful physical exploration and examination of the sputum, if not already made. The search of the sputum for elastic tissue is relatively less valuable, because bacilli are usually found much earlier.

In doubtful cases the tuberculin test may be made. I have found it very reliable in a number of cases, and believe it is without danger. E. L. Trudeau, of Saranac Lake, confirms this by his large experience, and says further, that tuberculosis of so moderate an extent as not to give any positive symptoms probably exists in 30 per cent. of individuals who have no reason to suspect its presence. One milligram of pure tuberculin is injected hypodermically, and if there be no febrile reaction in 10 to 12 hours, twice this quantity is used two or three days later, and gradually increased at intervals until five milligrams have been injected at a dose. If there be no rise in temperature within ten to twelve hours the patient may be considered free from tuberculosis. The usual rise is from two to four degrees F. Tuberculin should not be used where the diagnosis can be made without it.*

I cannot refrain from adding a word on the importance of securing the physical examination under favorable conditions early in the study of a case. Especially is this true of cases in which there is a hereditary tendency. It goes without saying, that the physical signs of incipient consumption may easily escape detection when an examination is made with the clothing on, while they would be easily recognized if the patient were stripped to the skin. Too frequently, also, an examination is deferred because of a fear that the patient will be needlessly alarmed thereby. So-called "hemorrhages from the throat" should be carefully investigated, as should also any continued hacking cough. Many of these coughs are now known to be due to tonsillar trouble, but this should not be taken for granted, and a careful examination of the throat should be associated with a physical examination of the chest. A habitually frequent pulse and rapid breathing should also excite suspicion. We should not omit either to examine the posterior part of the chest in the supraspinous fossæ, for it sometimes happens that physical signs are here detected before they are recognizable in front.

* Tuberculin is the concentrated glycerin extract of tubercle bacilli, and is made by evaporating a luxuriant glycerin bouillon culture of the bacillus to one-tenth of its volume. This is known as crude tuberculin, and while used as such for bovine inoculation must be greatly diluted for use upon the human subject. The crude extract is on the market, being prepared in Koch's laboratory in Berlin and by different commercial firms in this country. Dr. Ravenel, of the Laboratory of the Live Stock Association of Pennsylvania, prepares from the crude article made by him a stock solution for human inoculation. One cubic centimeter of this solution contains 0.1 gram of crude tuberculin in a one per cent. solution of carbolic acid. The latter is added in order to preserve the active properties of the tuberculin and to keep the preparation sterile. At the time of using, one part of the stock solution is diluted in twenty parts of sterile water, and then one cubic centimeter (15 minims) will contain 0.005 gram or 5 milligrams. Further dilution necessary to obtain the smallest quantity desired may be made at the time of using.

Prognosis.—The prognosis of chronic ulcerative phthisis varies greatly with different cases. Its duration extends over periods of from a few months to years.

A more important practical question is that of its possible curability and our power to defer the unfavorable end. That occasional cures from consumption take place cannot be denied; that there is such a thing even as spontaneous recovery must also be admitted. That such recoveries are infrequent and even rare does not alter the fact that they do occur. That much may also be done to put off the fatal ending of this very sad disease admits of even less dispute. Sooner or later, however, it is usually fatal. But we should not be deterred by this fact from using our best endeavors, not only to put off the end, but also to seek an ultimate cure.

(b) *Fibroid Phthisis.*

Definition.—This term is applied to a form of pulmonary consumption in which the lung, in addition to being the seat of tuberculosis, is permeated by an overgrowth of fibroid tissue. Its course is much slower, and while it often begins as an inhalation bronchitis in those exposed to the inhalation of fine particles of dust from various sources, it may also begin as an ordinary ulcerative or catarrhal phthisis.

Symptoms.—Its symptoms, on the whole, are less aggravated than those of ordinary phthisis. The cough is less severe, less exhausting, though more apt to be paroxysmal, and the patient has less fever and emaciates less rapidly. He is often able to pursue some occupation. Bacilli are less numerous and are found with greater difficulty. Expectoration is often, however, as copious, usually arising from cavities or dilated bronchi, and is more frequently fetid. It may contain fat crystals and Charcot's acicular crystals. There may also be hemorrhage. With the addition of these symptoms, and the presence of bacilli in the sputum, the clinical history is scarcely different from that of simple non-specific cirrhosis of the lung, from which it is, indeed, often separated with difficulty. As in this affection there may be hypertrophy of the right ventricle, induced by the extra effort demanded of the right heart to move the blood through the fibroid lung. Fibroid phthisis is especially characterized by its prolonged course, which may extend over years.

Physical Signs.—The degree of retraction of the chest wall as noticed by inspection is greater than in the ulcerative form, more easily recognized, and not always confined to the vicinity of the apices of the lungs. The heart is frequently dislocated and its apex correspondingly awry, sometimes to an extreme degree. If on the left side, owing to retraction of the lung, there may sometimes be seen a distinct cardiac pulsation in the second, third, and fourth interspaces. The intercostal spaces are often narrowed and the diaphragm may be drawn up. Modifications of vocal fremitus as revealed to palpation are not nearly so constant, being masked by the retraction and pleuritic complications, and may be absent. There is often little or no elevation of temperature.

Percussion is more constant in its results, there being marked dullness and a wooden-like resistance. The hypertrophy of the right ventricle referred to may extend the normal cardiac dullness in positive degree toward the right edge of the sternum.

Auscultation most frequently notes bronchial breathing and exaggerated

voice sound, but both of these may be lessened in intensity by a thickened pleural membrane. A dilated bronchus is frequently present, yielding the signs of a cavity, which may be found in the middle or even at the base of the lung.

To the signs of the fibroid state in one part of a lung are frequently added those of emphysema in the remainder or in the other lung.

Prognosis.—This is perhaps no better, so far as cure is concerned, than for the chronic ulcerative phthisis, but, as has already been stated, the duration of the disease is much longer, and under favorable circumstances much more can be done for the patient by the same treatment.

Treatment of Chronic Tubercular Phthisis.—There is no disease of like importance in which treatment must for various reasons differ so much in different cases. This is owing partly to the fact that curative measures must be adapted more or less to the circumstances of the patient, and partly to the varying peculiarities of the patient himself. In the following pages I will advise first, regardless of the patient's circumstances, the treatment which experience has shown to be most efficient, then recommend such measures as are useful or necessary under any circumstances.

The fundamental principle of a successful treatment of a case of tubercular consumption is *early diagnosis and corresponding promptness in the application of remedial measures, supported by the belief that consumption is not a hopelessly incurable disease.**

I. Climate Treatment.—Immediately after its recognition, or even, if possible, when the disease is threatened, the patient with tubercular consumption should be sent to a suitable climate, provided always that other necessary conditions of a wholesome and happy life can be secured. To discuss at length the relative value of such places would occupy more space than is justified in a text-book, but the following may be laid down as truths reached by those who have specially studied the subject: †

1. Tuberculosis is relatively rare in the following localities in the order named, viz.: On certain sea-coasts, such as that of southern California, including Santa Barbara, San Diego, Coronado Beach, and somewhat further inland, Los Angeles and Pasadena; on certain islands enjoying a nearly pure ocean climate, such as the Madeiras and Canaries; in desert places of wide extent, such as are found in the interior of continents, including the Nile Valley and Algiers; in polar regions; and, finally, it is rarest at high altitudes, its frequency diminishing with increasing altitude. The elevated plains of Colorado and New Mexico furnish pre-eminently the best conditions.

2. Animals successfully inoculated with the bacilli of tuberculosis develop the disease rapidly when confined, while those kept in the open air may escape entirely.

3. Damp, especially *cold* and *damp* soil, favors the development of tuberculosis, as do also variations in dampness when conjoined with changes in temperature.

4. Moist heat has no influence in producing the disease, but cases originating in tropical countries where the disease is prevalent progress rapidly.

5. Dryness of air is a positive advantage to the consumptive, while variability in a comparatively dry air has no prejudicial influence. Humidity

* For evidence of the correctness of this dictum see a paper by S. Edwin Solly, "Neglect of the Early Diagnosis and Treatment of Pulmonary Tuberculosis," "Med. News," February 4, 1802.

† See S. E. Solly's article "Climate," in Hare's "System of Therapeutics," vol. i. p. 415, Philadelphia, 1801.

apart from other factors is apparently without effect, either in causing the disease or curing it; for, although benefit has been received in a humid or sea climate, Solly considers it "probable that it is mainly due to greater purity of the air or the elimination of unsanitary conditions and hurtful occupations, as when an overworked citizen takes a sea voyage, or a Bostonian is sent into such a climate as the Isles of Shoals, or a Philadelphian to Atlantic City." Whatever the cause, the beneficial influence of a sea voyage to the consumptive is undoubted.

Where low climates are characterized by infrequency of phthisis it is by reason of dryness and uniformity of temperature, as is the case in lower Egypt and the Valley of the Nile in Central and Upper Egypt, and in the interior of Algiers as contrasted with the coast belt of that country, with Java, with the Gulf States of America, Mexico, Guiana, and some of the West India Islands.

That elevation is unfavorable to the development of consumption and favorable to its cure is abundantly attested, but there is some difference in opinion as to the degree of altitude at which these qualities are manifested, some placing it as low as 1500 feet, the majority at 2500 feet. The latter is probably the more correct, though there is reason to believe that different individuals as well as different stages of the disease may be differently influenced in this respect. For the most part dryness goes with altitude, so that the two conditions are commonly associated. How altitude operates independently of dryness is not easy of explanation, although it is probable that diminished atmospheric pressure is the potent factor. The method of its action is perhaps not precisely understood, but the immediate effect is increased breathing-rate and pulse-rate; next, an increase in the depth of each respiration, followed by cardiac expansion and by hypertrophy; and later, by a fall in the rate of breathing and pulse to the normal, as the depth of the respirations and the amount of blood passing through the heart at each contraction are increased.

The following classification, by G. A. Evans,* of the climates resorted to by consumptives may be found useful in making a selection of climate for a particular case:

1. Climate Cool and Moderately Moist, general elevation 2000 feet—Western slope of the Appalachian chain, Adirondacks, Catskill, Allegheny, and Cumberland Mountains.
2. Climate Moderately Warm and Moderately Moist.—Western North Carolina, Asheville, elevation 2250 feet; Western South Carolina, Aiken; Georgia, Marietta and Thomasville.
3. Climate Warm and Moist.—Florida, Southern California, coast region.
4. Climate Warm and Moderately Dry, elevation about 2000 feet.—Southwestern Texas, Southern California, inland.
5. Climate Cool and Moderately Dry, elevation about 1000 feet.—Minnesota, Nebraska, Dakota.
6. Climate Cool and Dry, elevation from 4000 to 7000 feet.—Montana, Wyoming, Colorado, Northern New Mexico, and Western Kansas. In this group are to be placed Davos and St. Moritz, in Europe.
7. Climate Warm and Dry, elevation 3000 to 5000 feet.—Southern New Mexico and Southern Arizona.

A further division of resorts in accordance with altitude is into *low*,

* "Handbook of Phthisiology," New York, 1888.

medium, and *elevated*. In the first of these fall naturally Florida, Georgia, and Southern California; in the second, places with an elevation of from 1500 to 2500 feet, including Asheville, the Adirondack and Catskill Mountains; in the third, altitude of 5000 feet and above, including the slopes of the Rocky Mountains from Wyoming down to Arizona in this country and Davos and St. Moritz in Europe.

As to the permanence of the curative results of treatment at high altitudes, it is a common impression among the laity that persons to retain the advantages gained in such climates must remain there. Of this Solly says: "I am firmly of the belief that persons cured in elevated countries have at least as good a chance of keeping well after returning home as those cured at sea level, and owing to the decided increase in general and pulmonary vitality imparted by the climate, probably a much better one."

The usefulness of sanitarium for consumptives has of late been conclusively demonstrated. Late observations would seem to show that less importance attaches to location of these sanitarium than has heretofore been believed, although it is reasonable to suppose, that sanitarium at high altitudes will furnish the most satisfactory results. *The keynote of success in these is the stringent hygiene and open air life.*

II. **Hygiene Treatment.**—The following should be carried out as far as possible in every case, whether the patient is enabled to make the change of climate advised or compelled by the force of circumstances to remain at home: Secure a habitation wholesomely located, free from dampness, avoiding low ground. The apartments occupied should be those accessible to sunlight for as many hours of the day as possible. In this latitude a south and west exposure obtains this condition. Provide the best possible ventilation for day and night. Especially at night sleeping chambers be thoroughly ventilated, as during the day the patient secures the effects of change of place, while at night he is compelled to remain in a single room. *The more nearly the air of the sleeping chamber approaches that of outdoors the more likely is the patient to improve.* Ventilation should be secured without subjecting the patient to drafts of air. A low temperature at night may be rendered less harmful than drafts of warmer air, since its effects may be counteracted by extra covering.

In addition to availing himself of a proper location and ventilation, the patient should spend as much time as possible out-of-doors, and except during active fever, in the practice of moderate exercise, due regard being had to its effect on the heart and breathing. No sudden or forced efforts should be made. For the most part the patient should be kept moving, although, if the weather is suitable, he may also sit for a time. Sunlight rather than shade should surround him in his outdoor life, and the temptation to sit down long for rest in cool, shady places should be resisted.

Daily bathing of the most thorough kind should be insisted upon, it may be with cool though not with very cold water. It should be followed by active friction, so as to maintain the skin functions at their highest point. Cold sea-bathing is not to be recommended, because the reactive power of consumptives is very feeble, and a chill of the body may be followed by permanently harmful results.

The body should be clothed in wool next the skin by day and by night, winter and summer. At night nothing is better or more convenient than a long flannel night-gown extending almost to the feet.

III. **Food** should be abundant and of the best and most nutritious kind.

Meats, including especially fats, poultry, game, oysters, fish, rich animal broths prepared in the most tempting way should be provided, because the quantity taken should be as large as can be digested and assimilated. Milk and cream, cheeses, and the like are eminently suitable. Koumiss or zoolak may be substituted for milk.

What shall we say of alcohol? It is in the majority of cases an efficient adjuvant in consumption, if properly used. That it is at times abused and that the alcoholic habit is sometimes acquired does not alter the fact that it is useful. The physician should watch its use as he does that of morphin. A moderate amount with meals in the shape of whisky improves digestion and increases appetite, while combined with milk and cod-liver oil it helps the assimilation of the latter and contributes to fat production—an acknowledged advantage to the phthical patient. He should be limited to a couple of glasses of sherry or as many tablespoonfuls of whisky at dinner, while a half-ounce morning and evening with a glass of milk will be as useful as a larger amount.

The whole purpose of the measures recommended under this heading is the production by improved nutrition of a soil prejudicial to the growth of the bacillus of tuberculosis. The effect of unhealthy location, dampness, bad ventilation, darkness, deficiency in fresh air and sunlight, filth of body, chilling influences, colds, improper clothing, and insufficient food is to favor such growth.

The treatment of consumption by *suralimentation*, as suggested by Débove, may be considered at this point. By it is meant surcharging the stomach with food through the stomach-tube. While it is true of the victim of consumption, as of no other disease, that he should be fed, the method does not seem reasonable. The introduction of food far beyond what the appetite calls for is usually attended sooner or later by a rebellion of the stomach. At the same time some happy results are reported. The method, as recommended, is to wash out the stomach with cold water and then introduce a liter (1 quart) of milk, an egg, and 100 gm. (about 3 1-2 ounces) of very finely powdered meat. This is done three times a day. It is much more rational to secure a natural appetite by fresh air and outdoor life. If, on the other hand, there be reason to believe gastric catarrh is present, an occasional washing out of the stomach may stimulate the appetite wholesomely. Or the vegetable bitters may be used for this purpose. Of these, the tincture of nux vomica in 20- to 30-minim (1.3 to 2 c. c.) doses before meals in cold water is one of the best. The compound infusion or tincture of gentian in two-dram (8 c. c.) doses is also excellent.

IV. Medicinal Treatment.—As to medicines, the remedy that has undoubtedly been of more use in the treatment of consumption than any other is really a food—cod-liver oil. When cod-liver oil is well borne it should be administered to every such case of consumption. When it is not well borne, that is, when unpleasantly eructated or causing indigestion, loss of appetite, or diarrhea, it should at once be discontinued, and if a cautious attempt to return to it is met with a similar experience no further trial should be made. In my hands the best method of administration is to place in a wineglass from two teaspoonfuls to a tablespoonful of whisky and overlay it with the same amount of cod-liver oil. It is then “tossed” into the back part of the throat, and after a little experience this is accomplished with great facility, while nothing is tasted but a pleasant residue of whisky. The maximum dose should be a tablespoonful twice a day. The best time is

immediately after breakfast and on retiring at night, although experience may determine more suitable seasons.

The various compound preparations and emulsions, consisting of cod-liver oil, other tonic substances, gums, and flavors to cover up the taste do not meet with much favor with me. At best they are but half oil, they are costly, and as a rule, in my experience, are no better borne than the pure oil. Occasionally they are better tolerated, and under such circumstances they should be administered. It should be remembered that the chief purpose of the whisky is not so much to cover the taste of the oil and to render easy its administration as to favor its assimilation and efficiency.

After cod-liver oil, more frequently in conjunction with it, I value creasote or its derivative creasotol. Creasote is not a specific for consumption, but it relieves the catarrhal symptoms and diminishes the cough and expectoration. There are various modes of administering it. One drop, as dropped from an ordinary bottle—not a dropper—equals very nearly 1-2 minim, and a minim weighs almost exactly a grain. A convenient shape is a gelatin-coated pill, of which 1-2 grain (0.03 gm.) pills and 1 grain (0.065 gm.) pills are made. Beginning with 1 grain after each meal and increasing 1-2 grain a day, a dose of 6 to 7 grains (0.39 to 0.45 gm.) three times a day is very easily attained, as a rule. I do not often exceed 5 grains (0.32 gm.) or 10 drops three times a day, lest the stomach be upset. One should seek, however, to reach at least this dose and keep it up with occasional intermissions. Another excellent mode of administration is in hot water immediately after meals, beginning with two drops or a minim at a dose and increasing up to 10 drops, which correspond very nearly to 5 grains (0.32 gm.). It may also be given in one of the bitter tinctures, or in any mixture with alcohol, or in emulsion, or with sherry wine. Cod-liver oil and creasote may be given conjointly—that is, the creasote may be incorporated with the oil before using.

Still better than creasote, though more expensive, is creasotol or carbonate of creasote. It has the great advantage of being unirritating and can therefore be given in larger doses. I begin with 10 minims (0.66 c. c.) and increase to 30 minims (2 c. c.) after meals, omitting it for a time at the end of every six weeks. It is conveniently given in capsules. Among those who report favorably on it is the Berlin clinician, Leyden.

Duotol or guaiacol carbonate is similar in its effect and is said to be better borne at times than creasotol. It is given in doses of 0.2 to 0.5 gram (3 to 7 1-2 grains) three times daily in capsules or wafers or dry on the tongue, followed by a mouthful of water.

I have never been able to secure happy results from the use of creasote by inhalation. It may, however, be employed in combination with chloroform and alcohol, to which tincture of conium is sometimes added to mitigate the irritating qualities of the vapor. A mixture of equal parts of each may be made and a few drops placed on the sponge of a Burney Yeo's inhaler, and inhaled as long at a time as possible; or 10 to 20 drops (0.6 to 1.3 c. c.) may be added to 7 drams (26.25 c. c.) of water and 1 dram (4 c. c.) of glycerin, and used in one of the numerous excellent forms of nebulizer now in use. Or it may be placed on the surface of steaming water, with the vapor of which it may be carried to the mouth by a suitable appliance. A little glass tube, open at both ends and filled with small pieces of pumice on which the substance to be inhaled is dropped, also serves the purpose fairly well.

It is probable that the inhalation at a single sitting has not been long

enough continued. The following, recommended by Clement A. Penrose,* has impressed me—creasote, oil of turpentine, each four drams (16 c. c.); comp. tr. benzoin, three ounces (90 c. c.); one dram to a pint of hot water. As the patient becomes accustomed to the fumes, more of the creasote and oil of turpentine is gradually added until the mixture consists of equal parts of the three ingredients. The inhalations, to be effective, should be systematic and of from ten to fifteen minutes' duration each. The above inhalation mixture may be combined with steam alone, with steam and oxygen, or with steam at home and with steam and oxygen at the office.

Iodin has long been a popular remedy employed by inhalation. A good way is to dissolve a few grains in an ounce of ether and to inhale the vapor with the mouth or nose over the vial for a few minutes at a time. The following combination may be used in the little pumice-loaded tube referred to: Compound tincture of iodine, glycerole of carbolic acid, tincture of conium, each a dram (4 c. c.); spirit of chloroform, enough to make an ounce (30 c. c.). The carbolic acid may be omitted, if desired, and other changes made. S. Solis-Cohen recommends the use of ethyl iodid placed simply in an ounce-vial, over which the patient places his mouth or nose and inhales for five minutes at a time. Or glass capsules containing five minims of the drug may be crushed in a cloth and then inhaled. He regards it as especially useful in ulcerative laryngitis and as assisting in the disinfection and healing of pulmonary cavities.

Iron is indicated in all consumptive cases, and it is generally well borne, but it should be given in much smaller doses than is usual. The bane of iron is its constipating effect, and this counteracts all the good it otherwise does, and in my experience the various preparations of iron do not differ materially in this respect. Such effect is not produced, however, if a proper dose is given, and if it constipates in the dose administered, this should be reduced until no such effect results. When this is attained it should be kept up with occasional intermissions. Five or six drops of the tincture of the chlorid of iron thus administered and kept up for a long time go a great way toward keeping up the strength and counteracting the tendency to anemia so characteristic of consumption. Other preparations of iron are: reduced iron, carbonate of iron, which may be given in the shape of Bland's pills, and the sulphate of iron. The vegetable salts of iron, the citrates and malates, are elegant preparations, and the same principle should be observed in their administration.

Arsenic is often useful in consumption and may be combined with iron or alternated with it. Many consider arsenic more beneficial than iron. It is not desirable to give very large doses, and five minims of Fowler's solution are a sufficient maximum dose. It is especially useful in small doses where there are gastric symptoms, and may be continued in moderate doses for a long time.

Strychnin is a drug that is very valuable in pulmonary consumption, more especially as a heart tonic. It should also be continued over long periods in doses of 1-30 to 1-20 grain (0.0022 to 0.0032 gm.) three or four times a day. Quinin is also at times very useful, especially when there is fever.

V. Serum Treatment of Tuberculosis.—The late J. T. Whittaker *

* "Johns Hopkins Hospital Bulletin," November, 1890.

† "Theory and Practice of Medicine," New York, 1893, p. 158.

correctly said: "The discovery of tuberculin established the first real epoch in the treatment of tuberculosis, as it constitutes the first actual address to its cause." This is none the less true in view of the fact that the first essays with it appeared to be absolute failures. There is reason to believe, however, that the continued use of it and antitubercle serum by certain courageous therapeutists—Whittaker, of Cincinnati, just quoted, Dennison, of Colorado, Trudeau, of the Adirondack region in New York, Karl v. Ruck, of Asheville, Maragliano, and E. A. de Schweinitz—may be followed by results that promise more than the earlier trials immediately succeeding Koch's announcement. This expectation is reasonable in view of the acknowledged efficacy of the serum treatment of other diseases, notably diphtheria.

Referring to the refined tuberculin of Koch, the "modified" tuberculin prepared by Trudeau, the watery extract of tubercle bacilli by von Ruck, or the antituberculin serum by de Schweinitz in Washington, the prospect of benefit to be derived from it is the greater the *earlier its use* in the disease, the *more localized the process*, and the *less general* the infection. It is contra-indicated in cases with decided fever, also when there is hemorrhage.

The dose of tuberculin administered should be short of that sufficient to produce a febrile reaction. The primary dose should be 0.2 mgm. hypodermically on alternate days, increased with every other administration 0.1 mgm. until a 2 mgm. dose is attained, when it may be increased more rapidly, say 0.5 mgm. every two or three days. After a 15 mgm. dose is attained the increase may be more rapid according to the effect produced until 0.05 to 0.1 gm. dose is attained, when it should be decreased by halving the dose at every injection and discontinue altogether at 0.01 mgm. The injection is best given in the back between the shoulders. The general guide as to dose is the body temperature, which should be taken for a week before treatment as a basis for comparison. A slight rise (1-2° to 1° F.) six to twelve hours after the injection is the signal that enough has been given, and the dose should not be repeated until the temperature again falls to the standard determined, after which the dose last given is repeated until it produces no fever.

The object aimed at is to get in as much tuberculin as possible, say up to 0.1 gm., so gradually as to produce only a little local and as little general reaction as possible. It is to be remembered that tuberculin can influence favorably only the tubercular element of phthisis and is powerless and probably injurious where any extensive and generalized complicating streptococcus infection has taken place. On this account the previous or concurrent use of antistreptococcus serum has been practiced with results somewhat encouraging. The injections of 10 c. c. are made at much longer intervals, say a week or ten days.

The antitubercle serum of de Schweinitz may be injected in doses of 1 c. c. on alternate days. By either remedy the treatment should be continued for six months, unless the disease is earlier arrested, or unless harmful results appear earlier. Late experience seems to show that the serum is to be preferred to tuberculin.*

VI. **Pneumotherapy.**—Where for any reason the advantages of high altitude are not available, some benefit may be derived from artificial pneu-

* See "Some Statistics upon Sero-Therapy in Tuberculosis." By J. Edward Stubbett, "Medical News," March 11, 1899.

motherapy, by which it is sought to modify the air breathed, more especially as to density, although such therapy may also include modifications in temperature, humidity, and chemical composition. The simplest application as applied to density is the producing of conditions by which the patient may be immersed in a compressed or rarefied air which he likewise breathes. The more usual application at the present day is, however, that of "pneumatic differentiation," by which the patient inhales air different in density from that which surrounds him.

In the differential method the object is also to facilitate inspiration or expiration, or both. Inspiration of compressed air favors inspiration, as does also expiration into compressed air. Expiration, on the other hand, is favored by inspiration of rarefied air and expiration into rarefied air. These objects are accomplished by the pneumatic cabinet, and very satisfactory results are claimed by some observers. The treatment is truly rational. But whether it be the result of inherent difficulties in the use of the apparatus or failure to accomplish what was expected, the use of it does not seem to grow in favor, and I doubt whether as many cabinets are in use to-day as ten years ago. To be efficient the apparatus should be used two or three times a day, with intervals of rest between, and unless the patient have it at his own home or be in a hospital provided with one, it becomes almost impossible to avail himself of it.

VII. Treatment of Special Symptoms.—Naturally, the first of these is cough, and there is no symptom that requires more judgment in its management. A slight cough is often best let alone, because it is an effort to remove secretion, the retention of which may be harmful. If a cough becomes harassing, so as to keep the patient awake or otherwise wear him out, it should be controlled. This should be done, if possible, by counterirritation. A simple capsicum plaster, or painting with iodine, or iodine with a little croton oil added, or a mustard plaster, or a turpentine stupe may answer the purpose when the cough is not too severe.

As to cough medicines, creasote and creasotol may be classed among the curative measures for this symptom, as they diminish secretion and thus relieve cough. Moderate cough is often easily controlled by simple syrupy remedies, such as syrup of wild cherry and syrup of tolu, to which some dilute hydrocyanic acid may be added, two to four minims (0.12 to 0.24 c. c.) to the dose. If these measures are not sufficient, an opiate becomes indispensable. It does not matter much what preparation is used. A teaspoonful of paregoric in the beginning is often sufficient, acting like a charm, or deodorized tincture of opium, if a stronger preparation be needed, will answer better because of its smaller bulk. For this reason, too, sooner or later, the alkaloids of opium are indicated. Codein is the best of these to start out with in doses of 1-4 grain (0.0165 gm.) increased. Heroin is the most recent and is much commended. It is given in doses of 1-20 grain (0.0033 gm.) or more. Morphin, however, becomes ultimately the best remedy in the majority of cases. When this stage is reached the wiser course is not to order it at stated intervals, but at such times as the cough needs especially to be controlled, as at night on going to bed, or once during the night. In the morning the patient should be allowed to cough for a time to get up the accumulated secretion. The dose essential for this purpose must vary, anything from 1-24 to 1-4 grain (0.00275 to 0.0165 gm.). Sometimes it may be combined with advantage with a syrupy preparation, which facilitates expectoration, and to this may be added a few drops of a mineral acid, as the

aromatic sulphuric. A cough medicine of this kind, long in use in Philadelphia, is as follows:

℞	Morphinæ sulph.....	gr. ss-ij	(gm. 0.033-0.066)
	Potass. cyanid.....	grs. iij	(gm. 0.2)
	Ac. sulph. aromat.....	f ʒ j-ij	(c. c. 4-8)
	Syr. prun. Virginian.....	q. s. ad	f ʒ iij (c. c. 95)
	M. et Sig.—Teaspoonful as often as necessary to quiet cough.		

In the morning when a patient has to contend with a cavity full of pus it is better to give him a tablespoonful of whisky or a milk punch, to aid in coughing up the accumulated matter, than to give a sedative cough mixture.

The ammonium preparations, chlorid and carbonate, are rarely useful in the cough of consumptives, while their effect is to derange the stomach and destroy the appetite. Sometimes, however, where there is much loose phlegm, the use of the former for a short time may be beneficial. Under the same circumstances terebene is one of the best medicines given in doses of 5 to 10 minims (0.3 to 0.6 c. c.). It taxes the stomach, however, somewhat severely. Terpin hydrate may be substituted in doses of 3 to 6 grains (0.2 to 0.4 gm.).

The fever of consumptives rarely demands special measures. Should the temperature exceed 103° F. (39.4° C.) there is no more satisfactory or harmless measure than sponging, allowing to remain on the surface a thin film of water, the evaporation of which produces the refrigerating effect. Or 3 grains of antipyrin or acetanilid or 5 of phenacetin (0.2 to 0.33 gm.) may be given, the effect watched, and the drug repeated two or three times if necessary. The high fever of phthisis rarely lasts long and of itself does little or no harm. It is merely a symptom of a more uncontrollable septic process.

Night-sweats do demand special measures. By far the most reliable therapeutic agent is atropin; 1-100 to 1-60 grain (0.00066 to 0.0011 gm.) at bedtime usually suffices. It may be combined with morphin, if the latter is necessary. Sponging at bedtime with a saturated solution of alum in alcohol is often efficient when atropin fails, or sponging with simple hot water may answer.

Agaricin or agaric acid in doses of 1-8 to 1-4 grain (0.0082 to 0.0165 gm.) is a modern remedy for night sweats. Camphoric acid, 20 to 30 grains (1.32 to 2 gm.) in a capsule at bedtime, is another remedy highly recommended. So are muscarin, 5 minims (0.3 c. c.) of a 1 per cent. solution, and picrotoxin, 1-60 grain (0.0011 gm.). An old remedy is the aromatic sulphuric acid, and it is certainly a good tonic, which, administered in doses of 10 to 20 drops (0.6 to 1.3 c. c.) before meals, may also aid in checking the sweats. Or the following lotion may be used: Balsam of Peru, 1 part; formic acid, 5 parts; chloral hydrate, 5 parts; trichloroacetic acid, 1 part; absolute alcohol, 100 parts.

Hemorrhage is an alarming symptom and must be treated, although it is probable that most hemorrhages stop of their own accord. The patient should be immediately put to bed at rest, with the shoulders raised. Ice, suitably encased, may be applied to the chest, or cloths wrung out in cold water. A hypodermic injection of 1-4 grain (0.016 gm.) of morphin to an adult is a useful measure to secure quiet. Indeed, I almost always begin treatment with it. If the pulse is full and bounding, 3 drops of the tincture of aconite may be given hourly until some effect is produced. Gallic acid may be given in doses of 15 grains (1 gm.) every half hour while the

hemorrhage lasts. The domestic remedy, common salt, is probably useful by exciting reflex contraction. A teaspoonful swallowed is the dose. When the hemorrhage persists hypodermic use of ergot is recommended. The best preparation for this purpose is a good quality of the fluid extract, of which 30 minims or a dram (2 to 4 c. c.) may be injected at one time, twice in the twenty-four hours. What is known as ergotin is probably a solid extract, of which 1 grain (0.065 gm.) is equivalent to 5 minims (0.3 c. c.) of the fluid extract.

Gelatin is as efficient in the treatment of hemorrhage of the lungs as in other hemorrhages. A very promising method is to administer hypodermically 100 c. c. of a 2 per cent. solution at a temperature of 110° F. (43° C.). The gelatin is also advised by the stomach, although it would seem that the effect of digestion would tend to destroy any hemostatic properties. Good results are, notwithstanding, claimed for it. It is certainly an easier and much less painful mode of administration. I am in the habit of ordering the usual homemade gelatin as prepared for the table, in wineglass doses every two to four hours. Suprarenal extract is also recommended in doses of five grains to the powder every two hours. Strapping is very highly recommended by William Gilman Thompson. He directs that pads of cheese-cloth be placed in the axillæ and over the femoral veins, and buckle-straps drawn over them tight enough to prevent venous return, but not to prevent arterial flow. It is best to strap but three extremities at one time, loosening one strap every fifteen minutes and re-applying it to the unstrapped limb. The compression may be maintained for an hour or two. Care should be taken not to loosen all the straps at one time.

The diarrhea of consumption does not generally become troublesome until tuberculosis of the bowel develops. Slight degrees seem often to relieve the cough. When there is tuberculosis of the bowel it is exceedingly difficult to control. Sufficient doses of bismuth are on the whole the best remedy—sufficient, because at first the smaller quantities, say 10 grains (0.66 gm.) answer, while later much larger doses are necessary. Opium is, however, often necessary, and sometimes the mineral astringents, as the acetate of lead, nitrate of silver, and oxid of zinc, act well in combination with it. Tannic acid is also efficient in combination with opium, and changes must be rung on these various remedies, as any one is apt to lose its effect.

VIII. Prophylaxis against Tuberculosis.—Accepted views as to the nature and causation of tuberculosis have raised the question of prophylaxis into one of paramount importance. Careful analysis of accumulated evidence in favor of the communication of tuberculosis goes to show that sputum dried and disseminated with dust in the atmosphere is by far the most important medium. After this the meat and milk of tuberculous cattle, though most recent studies, already referred to on page 241, go to show that it is doubtful whether tuberculosis was ever caused by the drinking of milk. The perspiration of the affected subject must be acknowledged to be a possible medium, since inoculation of animals by it has resulted in tuberculosis, while the sweat collected after washing and the use of proper antiseptics failed to produce the result. Kissing and the use of wind instruments and pipes previously used by tubercular subjects are possible media. It is claimed of meat and milk that they infect through the alimentary canal and the form of tuberculosis resulting from them is usually glandular, especially of the adjacent mesenteric glands. In like manner the tuberculosis traced to kissing has been in the glands about the neck. The discharges from skin tuberculosis

or lupus are also vehicles of infection. Mainly, however, we have to guard against sputum as an agent of infection, the other causes being comparatively easy of escape.

The first and most important measure is, therefore, the disinfection of the sputum. To this end a spit-cup should always be used when possible, and it should contain a germicide that will destroy the bacillus. The best of these germicides is corrosive sublimate, dissolved in water in the proportion of 1 to 1000 or 1-2 grain to the ounce (0.033 to 30 c. c.), and a small quantity of this solution should be placed in the spit-cup. In consequence of the fact that corrosive sublimate coagulates albumin, the tartaric or citric acid sublimate should be used. Next in efficiency is carbolic acid in proportion of 1 to 30 or 24 grains (1.6 gm.) to an ounce (30 c. c.) of water. A strong solution of soda or potash may be used. As already stated, sputum becomes practically active only when dried, pulverized, and carried into the air as dust. It is evident, therefore, that even water in the cup will render it harmless for the time being, while, if scalding water be substituted, its permanent destruction is secured. The first-mentioned methods are most efficient and should be practiced when possible. Such vessels should be further washed with scalding water and more germicide solution added at least once a day.

Under no circumstances should the patient be allowed to expectorate upon the floor, in cars or other public conveyances, or even, if possible to prevent it, in the street. In order to meet these necessities as well as those of other situations in the house where temporarily the use of sterilizing cups is impossible, the handkerchief is indispensable, but it should consist either of old pieces of muslin or linen, which can be burned after use, or of porous paper to be similarly disposed of. The so-called Japanese handkerchiefs answer the purpose admirably.

Dettweiler's pocket spit-cup, invented for use in the street or elsewhere as a substitute for the handkerchief, is an admirable invention. It is made of blue glass, is flat, and holds about three fluid ounces, or 90 c. c. There are two openings, one at the top and one at the bottom, both provided with

Fig. 25.—Pasteboard Spit-cup.

metallic screw-caps. The upper and larger opening receives a polished metal funnel extending half way down into the flask, and the whole is closed tightly with a spring cover or cap. The funnel acts like a similar appliance in certain ink bottles and prevents the spilling of the contents of the flask, even if the cap be left open. The lower opening is intended to facilitate the thorough cleansing of the flask. It is said that it can be made at a cost of less than 50 cents, and can be easily kept clean. The pasteboard spit-cups, supported in a rim of steel, recommended by the New York City Health Department, intended to be burned after use, are correspondingly inexpensive and answer the purpose very well.

To the same end, diminution of the possibility of harboring dried bacilli,

unwashable curtains and superfluous upholstery should be banished from the rooms occupied by tuberculous patients. There should either be no carpets, or they should be replaced by rugs that can be frequently taken up and shaken. The sleeping-car, with restricted air space *per caput*, its costly upholstery and curtains, used year after year, becomes a possible source of infection, especially in routes toward health resorts, but is less serious than it might be because of the short time that it is generally occupied by the tuberculous and healthy alike. The state-room of the ocean steamer stands a greater chance of being a medium of infection from its longer occupation.

When it is remembered how easy it is with ordinary intelligence and simple means to render completely innocuous the bacillus of tuberculosis, I do not myself believe it can be any more efficiently accomplished by the assistance of Boards of Health, and I see nothing to be gained by reporting tuberculosis as an infectious disease, like scarlet fever and diphtheria. I do not object to reporting consumption to Boards of Health, for statistical purposes, but am opposed to it with a view to surveillance by such Boards, because I believe it unnecessary, that nothing is gained by it, and that needless inconvenience, to say the least, is occasioned to victims and their families.

The second source of infection, the milk of the tuberculous cow, if it be a source, is avoided by boiling the milk, which is thus rendered thoroughly sterile. There are, however, objections to boiling milk. In the first place, the taste of boiled milk is not always agreeable, but of greater importance is the fact that it is constipating, especially when it is the only food, as in the case of children. It is desirable for this reason, therefore, to be able to use milk unboiled. That this is possible without harmful results was shown by some interesting experiments of Gebbard, who ascertained that the virulence of tuberculous milk is destroyed by dilution with the milk of other cows. Thus, milk from the udder of tuberculous cows was found to have lost its virulence when diluted in one instance 40 times, in another 50, and in a third 100 times. On the other hand, the dilution of sputum 100,000 times was found not to affect its virulence, while pure cultures do not lose virulence when diluted 400,000 times. An important practical conclusion is deduced from these experiments of Gebbard—viz., that a time-honored practice as to hand-fed babies of using only the milk from one cow is more dangerous than the mixed milk of a herd. For the chances of infection with such are much greater. Practically, the use by adults of raw milk mixed with other food cannot be regarded as dangerous, but with children fed exclusively on milk precautions should be taken to render it sterile by cooking, or if it must be used uncooked it should be the mixed milk of a number of cows. The milk of a cow known to be tuberculous should be invariably condemned and the animal slaughtered. The products of milk—that is, butter and cheese—are, of course, not amenable to the treatment to which milk can be subjected. Safety from infection from these sources can only be secured by a rigid inspection of cows, and by measures to prevent the development of tuberculosis in these animals.

Infection by tuberculous meat is still rarer. In the first place, the flesh of tuberculous animals may not itself be tuberculous, and, in the second place, the cooking to which meat is subjected must kill bacilli. On the other hand, that the communication of tuberculosis by tuberculous meat when carelessly used is possible is shown by the fact that tuberculosis has been produced in animals by the introduction of the juice of the meat of

other tuberculous animals and even from tuberculous human beings. The use of raw or half-cooked meat should therefore be prohibited.

In consequence of what has been said of the experimental production of tuberculosis by the inoculation of sweat as well as the increased possibilities of getting into the mouth portions of tuberculous sputum, no one should sleep with a tuberculous patient. Dishes and utensils used by such patients should not be used by others unless first scrupulously cleaned, and this is best accomplished by thorough boiling. The patient should himself be taught to prevent his hands, face, and bedding from becoming smeared with sputum.

Precautions against auto-infection are scarcely less important than those against infection of others. It has been said that if it were not for auto-infection most cases of tuberculosis, except those within the cranium, would get well. Be this as it may, it is certain that new foci of tuberculosis are constantly being developed in the same patient, which aggravate his complaint and hasten his death. Such a focus is tuberculosis of the intestine, which probably often has its origin in swallowed sputum. Patients should therefore be enjoined against the practice of swallowing sputum.

The close dependence of tuberculosis upon predisposition, hereditary or acquired, chiefly the former, has long been recognized. As to whether this or infection is the more important factor in the production of the disease cannot be regarded as settled. Thus, one authority, Volland, in 1892, declared that the greatest amount of good will be done by such treatment early in life as will correct any possible constitutional taint. Behrend, on the other hand, claims that our principal efforts are to be directed against the dangers of infection. Under the circumstances, a due amount of attention paid to both factors cannot be amiss.

It goes without saying that a tuberculous mother should not nurse her infant, but what should the child or adult predisposed to consumption do to avert the evil? The residence is the first consideration. If possible, the person should be reared in a country of high altitude. Such a course is much more likely to prevent tuberculosis than to cure it, if once acquired. Above all, he should avoid residence in houses situated in low, damp, and shaded localities. Bowditch's observations many years ago, already alluded to, showed conclusively that consumption is favored by these conditions. Further, such person should not reside in a house where many cases of consumption have preceded. And if it is impossible to avoid this the walls and floors should be thoroughly cleaned with the germicide solutions already mentioned. The rooms of the house should be large, airy, and well ventilated. The predisposed individual should sleep at night with windows and even doors open, due precaution being taken against drafts.

Outdoor life should be sought under all circumstances, avoiding, however, especially damp, cold exposure. Riding and driving should be practiced. Judicious athletics, such as develop all parts of the body in good proportion and especially such as secure expansion of the lungs, should be encouraged. Frequent inflation of the lungs should be practiced several times a day. Practice with dumb-bells and clubs of moderate weight is pre-eminently calculated to empty the deeper recesses of the lungs of retained mucus, and to cause the blood to move more rapidly through the more remote parts where the circulation is naturally sluggish.

The treatment of *acute* or *pneumonic phthisis* is supporting and stimulant, symptomatic and palliative. There is no advantage to be derived by

taking the patient away from home. Food and stimulants are required to combat the exhausting effect of the disease and its fever. The fever itself may be lowered by sponging and the cautious use of such apyretics as phenacetin, acetanilid, and the like, because in this form of the disease it is more apt to be continuous and exhaustive in character. The cough must be controlled by opiates, and such other measures must be taken as will make the patient comfortable and mitigate the sadness with which an inevitable fatal prospect is more or less associated. If it should happen that the disease assumes an unexpected chronicity, it may fall into a class of cases in which the treatment laid down for the more chronic forms of consumption is available.

IV. TUBERCULOSIS OF LYMPHATIC GLANDS.

SYNONYMS.—*Scrofula, or the King's Evil; Tuberculous Lymphadenitis.*

Etiology.—Even before the discovery of the bacillus of tuberculosis by Koch in 1882, it was generally conceded that what has been known as *scrofula*, or the King's Evil, was a true tuberculosis of lymphatic glands. The minute study of these glands showed the presence of miliary tubercles, and since Koch's announcement the bacillus has been found in them. The bacillus may be regarded as the immediate cause of the specific inflammatory process.

Tuberculous lymphadenitis is most common in children and young adults, but may occur at any age.

Symptoms.—The *glands* most frequently affected are those of the *neck*, which appear in various degrees swollen and tender, in many instances suppurating and rupturing when not opened by the surgeon's knife. The submaxillary glands are usually the first involved, but those in the posterior cervical triangle are also frequently invaded on one or both sides, though commonly on one side more than the other. The cervical and axillary glands may be conjointly involved, forming a continuous chain behind the clavicle and pectoral muscles. The bacillus usually attacks the glands nearest its point of entrance, and presumably the cervical glands are infected by bacilli, which enter by the way of the nasal or naso-pharyngeal passages. The vulnerability of these mucous membranes to the bacilli is, of course, increased by any inflammatory state present. As a rule, there is little or no constitutional sympathy in such a degree of invasion. There may, however, be slight fever.

More rarely there is involvement of *all the lymphatic glands of the body*. Such cases are sometimes met among negroes. In them are swelling, pain, and tenderness of all the visible glands, including the cervical, submaxillary, and axillary glands, while autopsy discloses the involvement of bronchial, mesenteric, and retroperitoneal glands. In such cases there is more or less continuous *fever*, but death is usually the result of some intercurrent disease, or of pressure upon the respiratory passages.

In addition to the visible pictures described, the bronchial glands are often involved without visible enlargement, the condition being first found at autopsy, when it may or may not be associated with lung tuberculosis. The enlargements may, however, reach such a size as to form a recognizable mediastinal tumor, which may or may not produce the signs of pressure. The bacilli which invade these glands filter through the respiratory passages.

Tabes Mesenterica.—When the mesenteric or retroperitoneal glands are especially involved the disease is called *tabes mesenterica*, or *abdominal scrofula*. These cases occur among children. The trunk and limbs are puny, wasted, and anemic, while their little bellies are prominent, partly because of the enlarged glands and partly from tympany, producing a striking picture. The tympanitic distention often predominates, making it difficult to feel the enlarged glands. In these cases, too, there is often *diarrhea*, with thin, offensive stools, yet the bowels are not generally the seat of tuberculosis. There may be tuberculosis of the peritoneum, which may also give rise to an uneven, nodular, tender, and painful enlargement easily recognized by palpation. The disease prevails among poorly fed children in the slums and badly drained and ill ventilated houses of the poor. There are fever, fretfulness, and a general aspect of abject misery. Death generally takes place through exhaustion; or some acute intercurrent disease, such as enteritis, carries off the little sufferers. More rarely adults may be affected with *tabes mesenterica*, either as a primary disease or as secondary to pulmonary tuberculosis. I well remember a case associated with peritoneal tuberculosis in which the diagnosis between this condition and carcinoma was difficult, the autopsy determining the question in favor of the former.

While tuberculous glands of the neck, and even of the axilla, tend to suppurate, the retroperitoneal and mesenteric glands more frequently caseate without suppuration, and especially characteristic is a tendency in the latter to calcify, furnishing a mode of healing of tuberculosis. The bronchial glands are also less prone to suppurate, but caseate and, at times, liquefy. The easier accessibility of the external glands to the pyogenic organisms may explain the greater frequency of suppuration in them.

Diagnosis.—The diagnosis of tuberculous lymphadenitis requires its differentiation from lymphadenoma (*Hodgkin's disease*), lymphatic leukemia, and simple lymphoma. The affected glands in tubercular lymphadenitis are usually more tender than those in *Hodgkin's disease*; they are more closely adherent to each other and the adjacent tissues, and are, therefore, more fixed and immovable than the glands in *Hodgkin's disease*. Again, tuberculosis rarely invades more than one group of glands, is associated with caseation and suppuration, while the lymphadenoid growths do not suppurate. Notwithstanding this, the tubercular process is slower. Tuberculosis affects the young—those of either sex under twenty—while *Hodgkin's disease* occurs at any age, is less frequent in the young, and is more common in males.

From *lymphatic leukemia* tuberculosis of lymph-glands is easily recognized by the absence of leukocytosis characteristic of the former. *Simple lymphoma* also affects a single group of glands, and is doubtless often mistaken for scrofulosis of the glands about the neck. The glands are, however, harder and less tender, less painful than tubercular glands, and there is less constitutional involvement, less anemia.

Sarcoma involves groups of glands, and spreads rapidly, invading also adjacent tissues, while *carcinoma* is always secondary to primary cancer somewhere else.

Prognosis.—The prognosis except in *tabes mesenterica* is generally favorable unless systemic infection occur, recovery being sometimes spontaneous. This is favored by suitable conditions to be mentioned under treatment. In former times "*scrofula*" was regarded as a protective against consumption. At the present day it is looked upon as a menace because of

the danger of systemic infection through it, and it is said that three-fourths of the cases of acute tuberculosis owe their existence to it. Under the circumstances we must regard cases of recovery from tubercular lymphadenitis in childhood as instances of a survival of the fittest. Certainly our present knowledge demands a prompt attempt to eradicate the local condition than was formerly practiced.

Treatment.—The general management of a case of tuberculosis of the lymphatic glands is similar to that of a case of tuberculosis of the lungs. The patient should be surrounded by the most favorable hygienic conditions, have the best of food, take cod-liver oil and the iodid of iron. The local use of iodin is undoubtedly efficient at times in dispersing these glandular swellings, probably by exciting an inflammatory process destructive to the bacillus, which in a general way is similar to the reactive effect of tuberculin.

When suppuration has set in it is best to open an exposed abscess with the knife, because if allowed to open itself there is apt to result an unhealthy sinuous ulcer, very slow to heal, and when healed causing marked disfiguration by unsightly cicatrices. The access of air permitted by the opening seems also to be antagonistic to the life of the bacillus, for with the healing of the abscess the tubercular process stops in that particular gland. Counter-irritation by any means seems to act similarly, although iodin appears to be the most efficient.

V. TUBERCULOSIS OF THE SEROUS MEMBRANES.

General tuberculosis of the serous membranes is a rare condition, and is recognized chiefly by the signs of tuberculosis of the peritoneum and, so far as they exist, of the pleura, these being the two serous membranes of greatest extent and importance.

Tuberculosis of the Pleura.

Tuberculosis of the pleura may be suspected when, along with the physical signs of tuberculosis elsewhere, there appear the signs and symptoms of a dry pleurisy. (See p. 542.) This is rendered still more likely if there be added the signs of pyothorax with fever, flatness on percussion, and the auscultatory signs of such effusion. (See Physical Signs of Pleurisy with Effusion.)

Tuberculosis of the pleura manifests itself—

1. As an acute primary inflammation characterized by a sero-fibrinous or purulent exudate. The onset of such an inflammation may be like that of ordinary acute pleurisy or it may be insidious in its development, like that of the latent form of pleurisy to be described under diseases of the pleura. It may immediately precede pulmonary tuberculosis, be associated with it, or succeed it.

2. As an acute pleurisy the result of extension from an adjacent tuberculous lung, and as such it may be circumscribed, adhesive, or may constitute an extensive sero-fibrinous or purulent pleurisy.

3. A chronic, adhesive, proliferative, tuberculous pleurisy characterized by great thickening and adhesion of the pleuræ, with tuberculous infiltration of the thickened product.

The symptoms and physical signs are in no way different from those to be described in connection with the non-specific forms of pleurisy.

Treatment.—Some time often elapses before an absolute diagnosis is made, after which, if the disease is at all extensive, its treatment is mainly surgical, consisting in drainage and washing out of the pleural sac. In some instances its complete success is secured only by excision of one or more ribs.

In addition the usual restorative and hygienic measures employed in tuberculosis of the lungs should be carried out.

Tuberculosis of the Peritoneum.

SYNONYMS.—*Tubercular Peritonitis; Tabes Mesenterica.*

Tuberculosis invades the peritoneum in two ways:

1. As a more or less diffuse deposit of miliary tubercles over the visceral and reflected layer, unattended by active inflammation.

2. As a tubercular peritonitis when the tubercular deposit is associated with an inflammatory proliferation more or less abundant. In a simpler variety of the latter, the *diffuse adhesive*, the peritoneal cavity is obliterated, the coils of intestine being matted together and adherent to the abdominal walls. In a second variety, known as *proliferative* peritonitis, there is marked thickening of the peritoneal layer with less tendency to adhesion and obliteration of the cavity. The omentum is sometimes an inch in thickness and composed of tubercular tissue in various stages of degeneration. The mesentery is similarly infiltrated and shrunken, drawing the intestines together into a *ball-like mass* or tumor as large as a child's head. The coats of the bowel, especially the large gut, also show localized areas of similar morbid changes. Tubercular peritonitis is sometimes associated with cirrhosis of the liver, whose capsule and that of the spleen may be infiltrated to enormous thickness. There is often in this form considerable effusion, which may be serous or purulent, at times bloody.

Symptoms.—The symptoms include those of chronic peritonitis, except that the abdomen is apt to be harder and more tender. Indeed, a *stiff and rigid abdomen* is quite characteristic of tubercular peritonitis. Later, however, is added, particularly in the upper part of the abdomen, the tympany so characteristic of peritonitis.

In connection with this must be taken the history of the patient, his appearance, the condition of the lungs and the presence of tuberculosis there and elsewhere, particularly in the pleura and bowel, whence extension to the peritoneum is easy by the lymphatic vessels. Four-fifths of all cases of tubercular peritonitis are said to succeed primary tuberculosis of the lungs. In children tubercular peritonitis is frequent as a part of a general miliary tuberculosis. By primary tuberculosis of the peritoneum is meant simply a tuberculosis in which no primary focus has been found elsewhere.

Diagnosis.—To the symptoms above described may be added, if needed for the purposes of diagnosis, the information to be derived from a test injection of Koch's tuberculin and an examination for tubercle bacillus of the fluid obtained by tapping. The rise of temperature succeeding the injection is almost infallible evidence, due antiseptic precautions being taken, of the presence of tuberculosis.

Treatment.—The treatment for tubercular peritonitis is the general treatment for tuberculosis, with such operative interference as may be deemed appropriate after a careful study of each case. The results of operation thus far have been quite sufficiently satisfactory to justify its repetition in suitable cases.

VI. TUBERCULOSIS OF THE GENITO-URINARY ORGANS.

This includes tuberculosis of the kidney and its pelvis, tuberculosis of the ureters and bladder, and tuberculosis of the ovaries.

Tuberculosis of the Kidney.

Morbid Anatomy.—Tuberculosis presents itself in the kidney in two forms:

1. In the shape of *miliary granulations*, which are a part of a *general tuberculosis*, giving rise to no special local symptoms.

2. As *primary foci of localized tuberculosis*, which in time may fuse to form larger areas that undergo caseation and liquefaction, transforming the whole kidney at times into a sac of purulent or cheesy matter. Such tuberculosis may start in the prostate gland, bladder, ureter, or pelvis of the kidney, and may extend also into the testicle and epididymis in men, and the ovary and fallopian tubes in women.

Symptoms.—The first form is without special symptoms. There may be none at all or *they may simulate closely those of nephro-lithiasis*. Those of the second, so far as the neighborhood of the kidney is concerned, are not distinctive or constant. There may be none or there may be *fullness, tenderness*, and even in extreme cases *fluctuation*. Frequently, subjective symptoms are reflected to the bladder, and they include frequent micturition, pain, and tenderness in the region of the bladder. There is also purulent urine, but commonly this differs from that of cystitis. It is more uniformly acid in reaction, and contains pus less admixed with mucus. Blood is much more frequent than in simple cystitis, and correspondingly albumin. Tube casts are very rarely found. Cheesy masses are sometimes present in the urine and with them the tubercle bacillus, which is the only pathognomonic sign. It should always be sought. The method for its recognition is the same as for the tubercle bacillus in sputum. It should not be confounded with the bacillus found by Malterstock, Travel, and Alvarez in the preputial and vulvar smegma. Hence, these parts should be carefully cleaned preliminary to the search. A negative result does not, however, exclude tuberculosis. In such event Damsch suggested inoculation with the pus from the urine into the anterior chamber of the rabbit's eye. At the end of three weeks tubercular nodules should make their appearance if the pus be tubercular. Sometimes, also, shreds composed of white fibrous and elastic tissue representing the disintegrating kidney or mucous membrane are found in the urine, but are not diagnostic, since they may be found in other varieties of destructive disease of the organ. The features of the urine described are almost characteristically intermittent—that is, the urine is sometimes almost or quite clear and again becomes purulent.

In the absence of such conclusive proof as bacilli in the urine, the presence of tubercle elsewhere, as in the lungs or nearer parts, as the testicles and prostate in men or the ovaries and fallopian tubes in women, affords

suggestive evidence. The latter may be investigated through the vagina and rectum, while catheterization of the ureters may also be practiced in women and stenosis of the ureter due to tubercular infiltration of the pyelo-ureteral wall thus recognized. Even in men the thickened ureters may rarely be felt through the abdominal wall. In other cases where the lungs are not primarily tubercular they may be secondarily invaded. Hydronephrosis, it is said, may result from complete obstruction of the ureter by tubercular infiltration.

Treatment.—Beyond the general restorative and palliative treatment useful in general tuberculosis there is no medical treatment of tubercular kidney. As soon as the diagnosis is made the surgeon should be called and nephrotomy done. Life is almost invariably prolonged by it, and if the operator be so fortunate as to find only a few isolated nodules on section, they may be scraped away. I have such a patient, a woman, thus operated upon six years ago by Dr. J. William White, who remains up to the present time quite free of a return of the disease. In cases in which the whole organ is involved a persistent renal fistula must be expected, if the kidney be not removed. Exploratory operation may even be justified under circumstances that must be determined in each case.

Tuberculosis of the Pelvis of the Kidney, Ureters, and Bladder.

It is not always easy to separate tuberculosis of these parts of the urinary tract. So far as symptomatology is concerned, outside of the bacteriological examination, the symptoms of tuberculosis are those of simple inflammation. If the disease is advanced there is tenderness, but this is the case also when there is impacted stone or pyelitis from other causes. The invasion of the bladder produces symptoms like those of cystitis, including frequent micturition and purulent urine in which there may be a small amount of blood. These symptoms, again, are not peculiar to tuberculosis, and the examination for bacilli again becomes necessary. This is much easier since the centrifugating apparatus has come into use. It must be remembered, however, that the presence of the bacillus in the urine tells us no more than that there is tuberculosis of this tract. We are still as much in want of information as to whether it comes from the pelvis of the kidney, the ureter, or the bladder. Cystoscopic examination may help us to locate the disease, but as often it does not do so. In women the catheterization of the ureter, if negative in one or the other ureter, tells us that the disease is probably located in the obstructed ureter. It is very important to remember that sometimes tuberculosis, and, indeed, any form of inflammation of the pelvis of the kidney, produces the same frequent desire to pass water as the same condition of the bladder, and that, too, when the bladder is entirely normal; so that we must not be too positive from the presence of this symptom that the bladder is the seat of infection, while, if there be tenderness in the kidney region and in the course of the ureter, these latter are more likely to be the seat of the disease. The diagnosis by exclusion may be of service. Thus, if we can exclude calculus and infection of the bladder and ureters by gonorrhoea, or in women by the milder infections which sometimes attend child-birth, the probabilities are increased that we have to do with tuberculosis. Suspected cases of tuberculosis of these parts are rendered more probable if the patient is a subject of pul-

monary tuberculosis. Primary tuberculosis of these organs is, however, possible.

Tuberculosis of the Ovaries, Fallopian Tubes, and Uterus.

A good deal of attention has been paid of late to tuberculosis of the ovaries by Wolff, Charles B. Penrose, Kynoch, and others. The ovaries may be the seat of miliary tubercles or may contain large cheesy masses. Ovarian tuberculosis is commonly associated with tuberculosis of the fallopian tubes. The symptoms of the former are in no way different from those of ovaritis from other causes. Fallopian salpingitis produces a hard and thick infiltration of the fallopian tubes, which may be recognized by the usual method of examination for disease of these organs. The uterine ends are commonly closed, while the intervening portion may be dilated and contain mucus, pus, and cheesy material. Tubal tuberculosis is commonly double.

Tuberculosis also invades the uterus, infiltrating it by miliary tubercles, which coalesce, soften, and break down, producing metritis and ulceration, discharges from which may contain the bacilli. Uterine tuberculosis usually begins in the region of the orifices of the fallopian tubes, and is really an extension of the disease from the tubes. It may, on the other hand, extend from below, from a tuberculosis of the vagina. The symptoms of the resulting metritis are the same as those of metritis from other causes. Tenderness and moderate enlargement may be named. Other symptoms, such as hectic fever and sweats, usually occur only when tuberculosis of these organs is a part of general tuberculosis. The disease makes its appearance more frequently during the period of greatest sexual activity, but it has been found in young children, and in them the ovaries and uterus have been found involved without participation of the fallopian tubes. It should be mentioned also that tuberculosis may extend from these organs to the peritoneum as well as from the peritoneum to them. Wolff * especially believes tuberculosis of the ovaries is not so rare as commonly supposed, since in 17 women who died of tuberculosis he found five in which the genitalia were invaded, and in three tuberculosis of the ovaries on both sides could be demonstrated.

Tuberculosis of the Testes, Prostate Gland, and Seminal Vesicles.

Tuberculosis of the testes and prostate is not infrequent. It presents itself as cheesy infiltration, which more frequently does not liquefy. More rarely, the vesiculæ seminales are invaded. The enlarged vesiculæ seminales may be felt through the rectum. The symptoms of this form of prostatic disease are in no way different from those of other diseases of the prostate with enlargement, until rupture takes place.

Tuberculosis of the testes is not such a rare affection. It is commonly secondary to that of the bladder and prostate, whence the bacilli travel along the vas deferens into the epididymis, which may be converted into a cheesy mass surrounding the testicle. With the invasion of the testicle further enlargement results with softening, ulceration, and fistulous burrowing. The walls of these fistulæ are infiltrated with tubercles. This malady is characteristically painless.

* "Centralblatt für Gynäkologie," No. 46, 1896.

The treatment of these conditions is mainly surgical, although the general measures usual in tuberculosis elsewhere are also suitable.

VII. TUBERCULOSIS OF THE MAMMARY GLANDS.

The mammary gland, though rarely invaded by tuberculosis, is nevertheless an occasional seat, Warden having collected 58 authentic cases in literature, nearly 90 per cent. of whom were females. Most cases developed in the third decennium. Others have found the disease more frequent during the child-bearing period. The bacilli causing the disease are probably carried by the blood from adjacent or surrounding organs. The special local product is a cheesy nodule in the gland, which softens, breaks down, and breaks through to the surface, often through the skin, with resulting fistulæ. Sharp, lancinating pains radiating into the arm are said to be characteristic. The tubercular nodules may be more deep-seated and hard or soft in consistency. Adjacent axillary lymphatic glands may be invaded by the infiltration. The finding of the bacillus is, of course, the crucial evidence, although the association of fistulæ and ulcers in connection with tuberculosis elsewhere suggests this disease.

VIII. TUBERCULOSIS OF THE HEART AND BLOOD-VESSELS.

History.—As far back as 1814, D. F. L. Kreysig,* in Berlin, said "Tubercular tumors of the heart walls, while met with very rarely, are very probable." In 1826 Laennec said the heart muscle is subject to tuberculosis. In 1832 Townsend, of Dublin, recorded a case wherein a large tuberculous nodule started from the left auricle and compressed the pulmonary vein. Virchow originally announced that tubercle differed from gumma in that it was not capsulated, but later Fuchs has shown that true tubercle may also become surrounded with a capsule.† It is probably more common than is supposed.

Tuberculosis of the Heart.—Tuberculosis of the heart presents itself in the shape of miliary tubercles scattered throughout the substance of the heart, more frequently in the membranes, causing tubercular pericarditis. The latter may be acute or chronic, more commonly acute, caused by sudden invasion. Both are usually a part of a general tuberculosis. Very rarely is the acute form primary. Tubercular pericarditis is followed by exudation of fibrin, and sometimes of blood and pus.

Tubercular pericarditis is found sometimes in old persons in whom it promptly causes death. In cardiac tuberculosis it is supposed that the bacilli arise from long latent foci of tuberculosis of the bronchial or mediastinal lymphatic glands. The latter, on the other hand, may be secondarily invaded from the cardiac tuberculosis. Such pericarditis is also commonly adhesive, and is not distinguishable by physical signs and symptoms from the other forms of pericarditis.

Tuberculosis also occasionally occurs in the papillary muscular substance of the heart.

Tubercles are sometimes found on the valves of the heart.

Tuberculosis of Blood-Vessels.—Tuberculosis may also invade the blood-vessels of a part attacked, and in tuberculosis of the lungs hemorrhages are commonly due to such invasion, which weakens the vessel and ultimately perforates it.

LEPROSY.

SYNONYMS.—*Elephantiasis Græcorum.*

Definition.—Leprosy is an infectious disease, due to the *bacillus lepra*, characterized by a subcutaneous and submucous nodular infiltrate, or by similar infiltration of nerve-trunks. The former constitutes tubercular leprosy; the latter, anesthetic leprosy.

History.—The disease is identified with the early history of Egypt and India, and is described in the Books of Moses, who gave many rules for its recognition, the isolation of victims, the test of recovery, and rules to be complied with before the convalescent could mingle with his people. It prevailed in Europe in the Middle Ages, but has become almost extinct there, except in Norway and Sweden, Hungary, and Roumania. In Greece and Turkey, Palestine, Syria, Egypt, India, China, Siam, the Sandwich Islands, and West Indies it is still endemic.

Etiology.—The bacillus of leprosy was discovered by Hansen in 1880, and subsequently clearly described by Neisser, and is especially characterized by its close resemblance to the tubercle bacillus. The bacilli are delicate rods whose length equals 1-3 to 1-2 the width of a red blood-disc. They are for the most part found in the interior of cells, rarely outside of them. Some of these cells are of large size and known as lepra cells. In the interior of these cells the bacilli often form clumps. They are exceedingly numerous in leprous tissue. They stain readily in anilin colors, but not in vesuvin, differing in this respect from tubercle bacilli, and also in that they liquefy coagulated blood serum, while tubercle bacilli do not. In the fresh condition the lepra bacilli exhibit active movement.

While the disease is contagious, its spread, under circumstances the most favorable, is exceedingly slow, the most intimate contact, as that between parent and child, being often unattended by inoculation. Experimental inoculation was, however, successfully performed on a Hawaiian convict by Arning, as well as in rabbits by Melcher and Artmann. According to Morrow, in the majority of cases the disease spreads by sexual intercourse, but cracks and fissures in the skin also favor the lodgment of the bacillus. In certain countries, especially the tropical, its spread is more rapid. Such are India, where there are said to be 250,000 lepers, and the Sandwich Islands, where, in 1889, there were 1100 in the settlement at Molokai. In the West Indies there are also many cases, and some remarkable morbid specimens from Trinidad were exhibited by Dr. Beaven Rake at the Pan-American Medical Congress, held in Washington, U. S. A., in September, 1893.

In this country the cases are for the most part isolated ones that enter by the seaports of the Pacific and Atlantic coasts. In Tracadie, on the Gulf of St. Lawrence, there is, however, a leper settlement, the disease having been brought from Norway in the latter part of the eighteenth century. The number of cases is being gradually reduced, there being in 1896 but 18 as compared to 40 a few years ago. This is apparently the result of segregation, which is now generally practiced where possible.

All ages and sexes are liable to this disease. Animals are not subject to it, although guinea pigs have been successfully inoculated. A curious impression has arisen that the disease is caused by eating spoiled fish or vegetables. To this view Jonathan Hutchinson has given the weight of his opinion. In view, however, of the acknowledged bacillary origin of the

disease, this can only be considered as a predisposing cause that lowers vitality by altering nutrition.

Morbid Anatomy.—Tubercular leprosy is characterized by its nodular outgrowths on the skin, the nodules being made up of a small-celled infiltrate, maintaining itself for a considerable time, after which it breaks down and ulcerates. The ulcers may heal, producing cicatrices. The mucous membrane is also invaded, particularly that of the eyelids, the conjunctiva, cornea, and larynx. Lymphatic glands, cartilage, liver, lungs, and spleen are also at times affected. The lepra nodes are vascular, differing in this respect from tubercles.

The morbid anatomy of the anesthetic variety will be included in the anatomical changes of the skin to be described in the symptomatology of that type of the disease.

Symptoms.—Nothing is known of a *period of incubation*. The outbreak of the disease is apt to be preceded by an *intermittent febrile movement*, which has been mistaken for intermittent fever and which may last for one or two years. There is often an *erythematous redness* of the skin, which in places becomes pale and in others assumes a brownish tinge. From this appearance the name *macular leprosy* has been applied to certain cases which go no farther. From these spots the pigment may also disappear, leaving perfectly white anesthetic areas—*lepra alba*.

In the *tubercular* form, which is the more common, an *infiltration of the skin* with *tubercular nodules* takes place. These remain for a long time intact, without degenerating, but sooner or later, as a rule, though often only after many years, softening and ulceration take place. Some of them, on the other hand, gradually disappear without ulceration. The number of nodules varies greatly. Some of them are pediculated, others are a simple thickening of the skin, which is conspicuous in such portions as the eyelids, nose, and ears, parts of which may disappear by ulceration. Even the cornea and conjunctiva may be the seat of nodules, and blindness may result.

The same development may take place in mucous membranes producing obstruction of the respiratory passages, including the nose and larynx. There may also be leprosy deposits in internal organs, including the liver, spleen, lungs, and lymphatic glands.

In the nervous or *anesthetic* form the peripheral nerves become infiltrated with the leprosy growth and are converted into thickened cords that may even be felt under the skin. These are at first painful, but later become anesthetic. Trophic phenomena of a striking character result, producing dryness, smoothness, and tightness of the skin with a total absence of nodules. Atrophy and wasting ensue from the same cause, and toes, fingers, and even larger limbs drop off. Great vesicles also sometimes form. Subsequently are added signs of weakness and exhaustion which gradually increase until the patient succumbs.

Diagnosis.—The diagnosis of the tubercular form is not difficult. The anesthetic variety resembles closely certain forms of *scleroderma*, but the trophic changes are more extensive. The resemblance of the early stage to intermittent fever has been referred to. The diagnosis may be made absolute by the detection of lepra bacilli in portions cut out for the purpose of study.

The anesthetic or nervous form of leprosy and *syringomyelia* bear a close clinical resemblance. The characteristic differences are thus pointed out by Laehr:* Leprosy is an infectious disease due to the *bacillus lepræ*, begin-

* "Deutsche med. Wochenschrift," January 17, 1897, p. 45.

ning with a febrile movement and primarily seated on peripheral nerves. Syringomyelia is a non-febrile or slightly febrile developmental disease, with its seat in the upper spinal cord. In leprosy the circumscribed anesthesia, muscular atrophy, and vasomotor-trophic disturbances of the skin, bones, and joints appear upon the face, trunk, and upper extremities and simultaneously or earlier in the lower. In syringomyelia the upper extremities are first affected, the lower very late, if at all, the face escaping, as a rule, completely. Sweating is absent in leprosy, but characteristic of syringomyelia. The wasting in leprosy involves first the muscles of distal parts of the extremities, while that of syringomyelia begins in the proximal portions. The anesthesia in leprosy includes pain sense, temperature sense, and tactile sense, while tactile sensibility is rarely involved in syringomyelia. In leprosy the anesthetic areas vary in form and extent, and, as a rule, are scattered over the entire body. In syringomyelia sensory changes show themselves on the trunk in the form of a girdle. The sensory disturbances correspond to the portions of the cord involved, while the anesthesia of leprosy depends upon local cutaneous disease and occasionally upon disease of the peripheral nerves. As a rule, it is possible to detect spindle-shaped thickenings of the peripheral nerves, especially of the ulnar and the peroneal, before the manifestations of neuritis are apparent. Altogether the symptoms of syringomyelia are similar to those of anesthetic leprosy, but in the latter disease the trophic changes are more marked, the phalanges often dropping off.

Prognosis.—The course of the disease is almost always prolonged, and the patient may die from intercurrent disease. In some cases death results from the gradual exhaustion of the system, which is more rapid in the ulcerative forms. From the nervous form of leprosy recovery does sometimes take place, though the secondary changes resulting remain permanent.

Treatment.—So far as known, treatment is unavailing. Segregation should be practiced whenever possible, for such a course is invariably accompanied by a falling off in the number of cases, and the continued practice of this method must ultimately result in the disease being stamped out.

Among the remedies that have been recommended are mercury and iodine by inunction. Internally are advised iodide of potassium, creosote and salicylic acid, chaulmoogra oil, and gurjun oil. The chaulmoogra has most reputation, and is regarded by Danielson after forty years' experience with it as distinctly useful. It is used in doses of two drams (8 gm.) every two hours, and gurjun oil in doses of ten minims (0.66 gm.). The latter may also be used by inunction.

RHEUMATIC FEVER.

SYNONYMS.—*Acute Rheumatism; Acute Articular Rheumatism; Inflammatory Rheumatism.*

Definition.—An acute febrile, infectious, but non-contagious fever, characterized by arthritis, usually multiple.

Etiology.—While no distinctive bacterium has as yet been isolated, Hermann Sahli found in diseased joints in which there was no suppuration a bacterium closely resembling the *staphylococcus citreus*, and Leyden a

diplococcus differing from that of pneumonia. Drs. F. J. Poynton and F. A. Paine with the diplococcus isolated from rheumatic fever have obtained in rabbits results which go to show that the organism with which they experimented is able to produce lesions of rheumatic fever, namely, mitral valvulitis, pericarditis, and polyarthritis. The diplococcus experimented with was obtained from the joints, from the throat in a case of rheumatic angina, from the bladder, and after death from the morbid product of rheumatic pericarditis and endocarditis. Again, by injecting a young rabbit with the organisms from the blood and cerebrospinal fluid of the infected rabbit they also produced polyarthritis and endocarditis in the second animal. Some of the animals recovered and others perished. In addition to the symptoms mentioned, there were wasting and involuntary clonic movements like those of chorea and the animal was also very nervous. With the chorea there was valvulitis.* In another instance the *micrococcus lanceolatus* was found. In view of the fact that several organisms have been found associated with rheumatic polyarthritis it may be true, as Flexner and Barker † suggested, that acute articular rheumatism has no etiological unity, but may be brought about by the entrance into the blood of one of several different pyogenic organisms under circumstances incompatible with the development of the phenomena of a general septicemia, but which may give rise to an inflammation of one of the several serous membranes, including the synovial, as well as the meninges, pleura, pericardium, or endocardium.

A predisposing cause seems, however, to be necessary in the majority of cases, and exposure to cold is the most common, although epidemics of acute rheumatism occur quite independently of such exposure. While sudden changes in temperature, also, often afford the needed conditions, the continued action of moderate degrees of cold, especially when accompanied by moisture, is almost as frequently responsible. If to these be added a lowered vitality due to insufficient food, fatigue, overwork, or all these combined, we include the majority of predisposing causes. The winter and spring, being the seasons in which the conditions of temperature and moisture operate most strongly, are those in which the disease is most prevalent. For a like reason it is more common in the temperate zones, the extreme North as well as the extreme South being for the most part exempt. In my own experience, the late spring finds many cases due to the cold and dampness of houses where fires have been prematurely dispensed with. It is a disease especially of young adults, being rare before fifteen and after fifty; while the exposing occupations, including those of driver, servant, and laborer, favor its development.

It may be still in place, in connection with the newer etiology, to mention two of the older theories of acute rheumatism. According to the *metabolic theory*, a morbid material is developed in the economy as the result of defective assimilation. Prout early named lactic acid as the peccant material, and more recently P. W. Latham has suggested a combination of lactic acid with other substances. The *nervous theory* was suggested by the late John K. Mitchell in 1831. ‡ According to it, the nerve-centers are affected by cold, and the local lesions are trophic in character, or defects of

* Communication to the Pathological Society of London, Tuesday, October 16, 1900; published in the "British Med. Jour.," October 20, 1901.

† "Am. Jour. Med. Sci.," 1894.

‡ "Am. Jour. Med. Sci.," viii., 1831, p. 55.

metabolism result from the primary nervous lesion, whence arises lactic acid, which accumulates in the blood.

Acute rheumatism is a disease simulated by other affections not infrequently called rheumatic. Thus, scarlet fever is often accompanied by a painful swelling of the joints due to the specific cause of that disease, and called rheumatic, when it should be spoken of as scarlatinal synovitis. The same is true of the so-called gonorrhœal rheumatism, which is not a rheumatism, but a gonorrhœal synovitis due to the gonococcus, and not a rheumatism accurately speaking.

Morbid Anatomy.—There is little to be added to what will be described in treating of symptoms, and to what is furnished by the complications, whose morbid anatomy will also be considered in connection with the diseases that constitute them. The synovial membrane is hyperemic and swollen, and in some cases the fluid in the joints is increased, is turbid, and contains flakes of lymph, rarely pus. There may be slight erosion of the cartilages. The fibrin of the blood is usually increased.

Symptoms.—While rheumatic fever is seldom ushered in by a *chill*, there is more frequently a short *prodrome* of a day or two, during which the patient feels uncomfortable or has an unpleasant aching feeling in his joints. More often, however, the *painful* arthritis, which is the first symptom to attract attention, develops rapidly, coming on in a single day or night, or seemingly in a much shorter time, making locomotion at once difficult or impossible.

The joint affection has some peculiarities. In the first place, the involvement is almost always multiple, and generally includes the larger joints, such as the knee, ankle, elbow, wrist, shoulder, and hip, although none are exempt, and the phalangeal and metacarpo-phalangeal articulations also suffer. The toe-joints escape most frequently. It rarely happens that a single joint is involved, but its occasional occurrence must be admitted. More rarely, if ever, does it happen that all are affected, although even the vertebral articulations must sometimes be included. The joint-inflammation is further characterized by a tendency to fly from one joint to another. Now it will be the elbow, then the wrist; again, the knee, and then the ankle or shoulder or hip, either on the same side or the other; but while there will be a reduction in the degree of inflammation, and correspondingly of pain in the relieved joints, the relief will not be total. On another day, again, the pain will have returned to the joint which had been temporarily relieved.

While the joint-affection always includes a synovitis, the process is by no means confined to the synovial membrane. The adjacent structures, including the capsular and lateral ligaments, and the tendons, with their sheaths, coursing over the joint, and even muscles, are all the seat of involvement, contributing to the swelling and to the pain by the exudation pervading them. Comparing two hands, one of which is involved and the other not, one can often see the depressions between the metacarpal bones in the former obliterated by swelling, while they maintain their usual distinctness in the latter. It is for such reasons that I prefer the name *acute rheumatism* to that of *acute articular* rheumatism, which would limit the process to the joints. Rheumatic fever is probably the best term.

Finally, mention should not be omitted of the non-articular rheumatic fever to which Kohler* has called attention, in which there are no joint-symptoms.

* "Zeitschrift f. klin. Med." Bd. xix. 1891.

The *pain* is almost always extremely severe, making all motion an agony, while jarring of the bed, or even the weight of bed clothing, may cause the patient to cry out with pain. To diminish the tension, which aggravates the pain, the patient is disposed to lie with all the limbs semiflexed.

From the beginning there is *fever*, but being seldom high at this stage, it is not commonly the first symptom to attract attention. Later, it usually increases proportionately to the extent of joint involvement, but only in the meningeal form is it extremely high. Nor does it pursue a course at all distinctive. In one case, for example, the temperature remained at 102° F. (38.8° C.) and a fraction, night and morning and throughout the day for a number of days. More rarely it rises to 104° F. (39.9° C.) Occasionally, however, there is intense hyperpyrexia, when the temperature rises rapidly from 104° F. to 110° F. (39.9° C. to 44.3° C.), and even higher. With this are associated cerebral symptoms of an alarming and dangerous kind, intense headache, and delirium—symptoms otherwise rather unusual in acute rheumatism. To these are often added unconsciousness, pulselessness, and cyanosis, rapidly followed by death, unless the temperature is promptly reduced. The sudden onset of these symptoms adds to their alarming character. This combination of severe symptoms is known as the meningeal form, or *rheumatism of the brain*.

The *pulse* in rheumatic fever is rapid, often disproportionately so to the fever, probably because of the nervous demoralization caused by the acute suffering.

Next to the fever and joint-inflammation, the most distinctive symptom of acute rheumatism is the *sweating*, which is copious and usually acid in reaction, sometimes even to such an extent as to impart an acid odor to the air of the room. *Sudamina* are a frequent consequence of such profuse sweating.

Discolorations of the skin, varying in intensity and character, make their appearance in certain cases. There may be a simple diffuse erythema, or it may be papular or tuberculated or marginate. There may be true *urticaria*, or there may be extravasations of blood, *purpuric* patches of such extent and depth as to result in sloughing of the tissues, hemorrhages from the mucous membranes, and hematuria. In one case under my observation there ensued permanent blindness from extravasation into the retina. These cases of *peliosis rheumatica* are not acknowledged by all to be truly rheumatic, the joint-affection being declared to be of a different nature, analogous to that of scorbutus and hemophilia.

The *urine* is also somewhat characteristic. It is scanty, of high specific gravity, very acid in reaction, and deposits a copious sediment of pink-hued mixed urates.

Very interesting and characteristic are certain *subcutaneous nodules*, attached to tendons and fascia, which have long been observed as occasional events in connection with acute rheumatism, and have been especially studied by Barlow and Warner. They vary in size from a shot to that of a pea, and may be numerous or but few. They occur on the fingers, hands and wrists, elbows, knees, scapulæ, spines of the vertebræ, and more particularly after the acuteness has passed away. They may last a few days or for months, and are more common in children than in adults.

Disposition to recurrence must be mentioned as a characteristic feature of acute rheumatism. Quite rarely does a person who has had one attack escape another, and it is these successive attacks which, augmenting pre-

vious cardiac lesions, finally cripple the heart until its work is greatly hampered. The intervals between successive attacks are various,—from a year to four or five years,—and they are the more frequent and more liable to occur the younger the subject.

Complications.—Very interesting in connection with acute rheumatism is the frequent involvement of the *serous membranes* other than those of the joints, such as the pleural membranes and the peritoneum. The involvement of the former simulates pleurisy and the latter peritonitis, and I well remember a case of my own, a girl of eight years, in whom for days I thought I was dealing with peritonitis, when a few doses of salicylate of sodium relieved my anxiety by promptly arresting the disease. In rheumatism of the pleura the absence of physical signs aids in the diagnosis. These phenomena are easily explained with the modern views of the etiology of rheumatic fever, since we have only to suppose the infectious material circulating in the blood to lodge upon the serous membranes instead of the joint tissues.

Of the same class is a much more common complication, *cardiac disease*, including endocarditis and pericarditis, the former being by far the more frequent, and confined almost exclusively to the left heart. Again, the mitral leaflets are much more frequently attacked than the aortic. While the cardiac involvement bears some relation to the severity of the disease, the mildest cases may become complicated as well as the severest. Hence, the heart should be daily examined, and for the further reason that the approach of the disease is often exceedingly insidious. On the other hand, cardiac oppression and palpitation may occur without actual structural change, and even a functional murmur may be present in acute rheumatism, and this, too, not only at the base, but also at the apex of the heart, an unusual site for such a murmur.

The proportion of cases in which cardiac complications occur, though difficult to estimate, is not less than 25 to 33 per cent. for endocarditis, with 10 per cent. more for pericarditis, making in all 35 to 43 per cent., while some estimate even a larger proportion.* Young subjects are more vulnerable than adults, and Fagge mentions an interesting difference in the sexes after adult life, which is, that *pericarditis* is more frequent in men above twenty-five than in women of the same age, probably because at this age men work much harder than women.

The variety of endocarditis is usually the verrucose, or warty, ulceration, laceration or perforation of the valve flaps being very rare. The malignant form of endocarditis does, however, occur. While the endocardial murmurs in the endocarditis of acute rheumatism are commonly soft, the pericardial murmurs are often loud, rough, and rasping, and the vibration resulting from the friction may even be communicated to the hand laid upon the precordium. Both conditions may result in complete recovery, but the former more commonly is the beginning of a chronic valvular defect.

Acute myocarditis is a fatal, but fortunately rare, complication of rheumatic fever, occurring alone or in association with endocarditis and pericarditis. It is commonly first discovered at the autopsy, though severe epigastric or precordial pain, embarrassed respiration, and cyanosis may suggest it. It probably occurs more frequently than is reported, although the facts do not substantiate it.

* De Lancey Rochester in a paper published in the "Jour. of the Am. Med. Assn.," December 15, 1900, says 60 per cent. for endocarditis and 10 per cent. for pericarditis.

Other complications of rheumatism are probably also the direct result of the poison. They include the inflammation of the serous membranes mentioned, bronchitis, and, more rarely, pneumonia. Convalescence from the latter is said to be slow.

The *sequelæ* directly traceable to acute rheumatism are also few. Chorea, acute nephritis, and exophthalmic goiter are among those so regarded. The nephritis is, perhaps, better considered a complication resulting from the same cause, just as are the endocarditis, pleurisy, and peritonitis. Among *sequelæ* should be included the more unusual one of chronic arthritic changes identical with those of chronic articular rheumatism and even rheumatoid arthritis.

Diagnosis.—The diagnosis of acute rheumatism is seldom difficult, the multiple painful involvement of the joints, the fever, and sweating seldom mean anything else; but pyemia and scarlatinal and gonorrhœal arthritis must be remembered as possible events. It is the monarticular variety which demands most discrimination in its determination. Traumatic synovitis, tuberculosis or white swelling, and the so-called nervous arthropathies are to be eliminated.

It is not always easy at a first visit to distinguish gout from acute rheumatism, but the most serious possible error in diagnosis is to mistake a pyemic arthritis for a rheumatic arthritis. This is not an uncommon mistake where there is no evident surgical lesion to suggest it. Osteomyelitis is said to be the most common cause of such pyemias; but other bone-diseases, puerperal sepsis, and gonorrhœa are also causes.

Prognosis.—The course of acute rheumatism is characterized by many fluctuations independent of treatment, and its duration is various. Sooner or later recovery generally takes place, although it may be with a crippled heart and a susceptibility to return. More rarely the attack passes over into a subacute condition which makes the patient a sufferer for a long time, while still more rarely true chronic rheumatism is the result. It used to be said the cure for inflammatory rheumatism is "six weeks," and though this is not true of every case, many are prolonged to quite this length.

Subacute Rheumatism.

This term is applied to forms in which all the symptoms are less marked and more prolonged. The fever is not so high, ranging from 99° to 101° F. (37.2° to 38.3° C.). The inflammation of joints is not so intense and the joints involved are less numerous. It exhibits the same "flying" tendency. It may also be associated with the cardiac complications, especially in children. It may pass into the chronic form.

Treatment.—Whatever may be the drawbacks to a successful treatment of acute rheumatism,—and they are many,—it is certain that most of those who had to treat this disease a quarter of a century ago now attack it with much more confidence than they did in that day. The drug which is responsible for this feeling is salicylic acid, and very few physicians think of any other at the outset of a typical case. The introduction of salicylic acid as a remedy for acute rheumatism is commonly ascribed to Buss, of Basle, some time prior to 1876, but attention was first prominently drawn to it in the latter year by Dr. Stricker, of Traube's clinic in Berlin.

Salicylic acid and salicylate of sodium are equally efficient, but the former has been largely superseded by the latter, because less irritating and

easier of administration. Still better borne is strontium salicylate. Whichever is used, there is one necessary condition of its efficiency, and that is its constitutional impression. The aim in the administration is, of course, to relieve the patient, but this effect is seldom obtained, or, if obtained, is of fleeting character, until the peculiar ringing in the ears is secured. To do this in the adult 1 1-2 to 2 drams (5.8 to 7.7 gm.) of salicylic acid and from 2 to 3 drams (7.7 to 11.6 gm.) of the sodium salicylate in the first twenty-four hours are required. If the salicylic acid is given, it should be in capsules or compressed pills containing 7 1-2 to 10 grains (0.49 to 0.65 gm.) every two hours, followed by a little water or milk. The salicylate of sodium may be given in doses of 10 to 15 grains (0.65 to 1 gm.) in solution every two hours, or every hour if the pain be severe, until relief comes, after which it should be kept up until the toxic effect is produced, when the dose should be diminished, but the drug continued; or the interval may also be prolonged. Others would give the salicylate of sodium, 1 to 1 1-2 drams (5.8 to 7.7 gm.), in a single dose, but in my experience few stomachs will submit to such quantities. The doses laid down may be pushed more rapidly if the suffering is extreme, but I have seldom found it necessary. Under this treatment the pain fades away, the swelling diminishes, and the anxious expression of the patient is changed to one of comfort in from twenty-four to forty-eight hours. Those who object to the salicylate treatment do so on the ground that the relief is not permanent, and it must be admitted that relapses do occur. I am confident, however, that this is often due to the fact that the remedy is discontinued too soon. As stated, the drug, while it should be cut down with the appearance of relief and toxic effect, must be continued for some time after relief is obtained.

Salicin, first used by T. J. Maclagan, appears to be about as efficient as salicylic acid, given in 20-grain (1.33 gm.) doses every two hours, in suspension or dissolved in warm water. It is much less irritating than salicylic acid, but has not superseded it on this account.

We should not, however, rely wholly upon the treatment by salicylates. Warmth is commonly a useful adjuvant, and to this end the joints and limbs should be kept surrounded by warm flannels or carded wool or cotton. The patient should, further, sleep between blankets and in a flannel gown so made that it may be easily removed, with split sleeves and split skirt, because of the extreme sensitiveness of the sufferer. The bed, if possible, should be narrow because of greater convenience in handling. The opposite plan, treatment by cold, is also recommended by some.

Sometimes the salicylates cannot be tolerated by the stomach, even in the smallest doses likely to be useful. They may then be given by injection as follows: The rectum is washed out with warm water, and after a short rest, 20 to 40 grains (1.3 to 2.6 gm.) or more of sodium salicylate in solution are injected well up into the bowel. This may be done once in six hours with the happiest result, as I can attest from personal experience. If larger doses are thus given, 90 to 120 grains (6 to 8 gm.) being recommended by some, it is well to guard them with a little tincture of opium.

But the salicylate treatment is not always successful, and sometimes the drug is not well borne in any shape. Then the oil of wintergreen, which contains 90 per cent. of salicylate of methyl, may be tried, in doses of 10 to 15 minims (0.6 to 1 c. c.) every two hours, in capsules or in emulsion. Or it may be alternated with the salicylate, if it be a question of tolerance of the latter, the gaultheria being usually better borne for a time by the stomach. I

say for a time, because, however pleasant wintergreen is at first, its continued use is apt also to excite disgust.

Oil of gaultheria is also used locally, at times with excellent results. It may be used as an embrocation in the proportion of one part of oil of gaultheria to two parts of olive oil. More usually it is applied to the affected joint on lint, which is thoroughly moistened with the oil, wrapped about the joint, and surrounded by gutta-percha, oiled silk, or other impermeable covering to prevent evaporation. This is further prevented by bandaging the whole limb. That the salicylate of methyl is thus absorbed is seen from the fact that salicylic acid appears in the urine a few days later, while the usual evidence of the physiological action of salicylates—viz., headache or fullness of the head with ringing in the ears—takes place. In view of the gastric disturbances which the salicylates cause in some persons, this mode of administration should not be overlooked.

The *alkaline treatment* of acute rheumatism, most relied upon before the salicylic treatment came into vogue, is a treatment which is by no means worthless. This, originally instituted by Sir A. Garrod, received an additional impulse from the late Dr. H. W. Fuller, who insisted upon the administration of such doses as secured and maintained an alkaline reaction of the urine. This is accomplished by sufficient doses of almost any of the alkaline salts, as potassium citrate, potassium acetate, sodium carbonate; or *liquor potassæ* may be used. Twenty grains (1.33 gm.) every two hours of the first three are generally sufficient, or 20 minims (1.3 c. c.) of the last. The dose may then be reduced, but enough should be given to maintain the alkalinity of the urine.

Failing for any cause in the treatment with salicylic acid, the alkaline treatment, or what is called the "mixed" treatment, may be employed. By this is meant the combined alternate use of the salicylates and alkalies. This may be tried, for example, where sufficient doses of the salicylates are not well borne by the stomach, when they may be supplemented by alkalies.

While using the alkaline treatment before the salicylates came into use, it was quite usual to combine with it the "flying" blister, one of small size,—say an inch square,—and to apply it now to one joint and then to another. That this practice is efficient in relieving pain there can be no doubt, while there is also reason to believe that it sometimes cuts short the inflammation in the joint treated. It is more than likely that this treatment has been too much neglected since the salicylates have become popular. In the subacute and chronic stages of the disease counterirritation by blisters or iodine is also of service.

For the relief of pain, opium or its derivatives is sometimes necessary, but less frequently than before the introduction of salicylates. Here, again, the hypodermic injection of morphin, 1-4 grain (0.016 gm.), is most comforting, but the Dover's powder in 10-grain (0.6 gm.) doses is often efficient. Phenacetin, acetanilid, and exalgin may be used for milder degrees. It is soothing to have the joints enveloped in cotton or wool.

The treatment of the *hyperpyrexia* of acute rheumatism must be prompt and energetic, as the danger to life is imminent, the extraordinarily high temperatures thus encountered being inevitably fatal in a few hours. There is but one treatment. It is the application of cold. The bath is to be preferred, although in its absence affusions of ice-cold water and rubbing the head and body with ice may be substituted. As soon as the temperature begins to mount rapidly above 105° F. (40.5° C.) it should be used, and if

delirium or unconsciousness is associated with such temperature, its need is even more imperative. When time permits, the application of cold may be more gradual. Thus the patient may be put in the bath at 70° F. (21° C.) and the temperature further reduced, if necessary, by the addition of ice or colder water. As stated, there seems now to be no doubt about the propriety of this treatment. Numerous cases of recovery have been reported, some even where the temperature had reached 107°, 108°, and even 109° F. (41.6°, 42.2°, 42.7° C.). With the reduction of temperature, the cerebral symptoms gradually disappear.

As the disease becomes more subacute or chronic, the necessity for more active local associated with tonic treatment becomes urgent. It would seem that at such stage the pathogenic cause has exhausted itself, and the disease has become more a local one, maintained by the dyscrasic state of the blood, itself brought about by the prolonged suffering. Hence roborant treatment with iron, arsenic, cod-liver oil, wine, and nourishing food becomes necessary. Indeed, the patient with acute rheumatism should be well fed throughout. Counterirritation by iodine or by blisters should be kept up with appropriate intermissions, although the results are often slow in appearing. Massage is especially valuable, and often surprisingly soothing ultimately, even although at first somewhat painful, while by it the mobility of the joints may be gradually restored. There results sometimes in the muscles in the neighborhood of the joint, and especially in the case of the shoulder, a paretic state, which is also benefited by massage, especially when associated with electricity.

Allusion may be made to remedies now more or less obsolete which have had some reputation in the treatment of acute rheumatism. Nitrate of potassium was among the most popular of the older remedies. As much as 2 drams (8 gm.) of the latter were given by Brocklesby three and four times a day. It was revived by Basham, who applied it locally to the inflamed joints. It is diuretic and diaphoretic. Guaiac is also one of the older remedies still used in chronic rheumatism, which see. The bromid of ammonium had the indorsement of J. M. Da Costa in the quantity of 1 to 1 1-2 drams (4 to 6 gm.) in twenty-four hours.

It should be mentioned also that no less eminent authorities than Sir Alfred Garrod and the late Austin Flint, Sr., thought acute rheumatism was self-limiting, and that it terminated about as quickly without medicines as with them.

Diet in Rheumatic Fever.—The diet of the patient with rheumatic fever should be simple and easily assimilable, but nourishing. While there is fever the food should be liquid, but the rule of conduct should be: feed well—do not starve.

INFECTIOUS DISEASES OF DOUBTFUL NATURE.

EPHEMERAL FEVER—FEBRICULA.

SYNONYMS.—*Irritative Fever; Gastric Fever; Simple Continued Fever.*

Definition.—A fever of short duration, depending on a variety of irritative causes. A febrile movement, lasting twenty-four hours and disappearing, may for convenience be called *ephemeral fever*; if of three or four days' duration, *febricula*.

Etiology.—The most frequent cause of this form of fever is probably the irritation of foods difficult of digestion, either by their inherent qualities or by reason of some temporary functional derangement of the stomach. In a word, indigestion is perhaps the most frequent cause of such a fever. This is especially the case with children, in whom the condition is often spoken of as gastric fever.

Another cause is probably exposure to cold insufficient to produce a bronchitis, tonsillitis, or other affection, too slight to be recognizable by the usual signs. Undue exposure to the sun, too, may produce it, or even fatigue. The inhalation of noxious gases is a possible cause, though somewhat discredited by recent studies;* also, the absorption from the stomach and intestine of lower toxic albumoses from putrid or decomposing foods—auto-intoxication by ptomains.

It is possible, too, that the germ of an infectious disease or its toxic products may enter the economy in quantity insufficient to develop the specific affection which is its usual result. Possibly the poison of rheumatism or malaria may operate in this way.

Symptoms.—The symptoms of irritative fever are those usual to fever in mild degree, *i. e.*, moderate elevation of temperature, rarely above 103° F. (39.4° C.), frequent pulse, headache, a sense of lassitude and weariness, loss of appetite, nausea, and restlessness; in children perhaps delirium. The fever is apt to terminate suddenly by crisis on the second or third day.

Diagnosis.—The diagnosis resolves itself into this: where a careful search fails to reveal the action of a cause, save one of those referred to, and no symptoms develop characteristic of any of the recognized diseases, the affection is irritative fever.

Prognosis.—Always favorable.

Treatment.—Rest in bed, a simple aperient, a fever mixture consisting of solution of citrate of potash, sweet spirit of niter, solution of acetate of ammonium or aconite tincture, will suffice to break up the fever and insure recovery.

PROTRACTED SIMPLE CONTINUED FEVER.

Definition and Etiology.—It seems necessary for the present to continue this term for a feverish process of a longer duration than ephemeral fever or febricula,—a fever that is not typhoid, not influenza,—lasting from two weeks to three months, and without definite lesions. Knowing, however, what we do know, and limited as our knowledge still is of infection, it is more than likely that some day a specific cause will be found for each of a motley group of such fevers, which will give them a definite name, just as cases formerly thus grouped are now relegated to typhoid fever.

Some of these cases, too, may belong to the group covered by the term *cryptogenetic septicemias*, suggested in 1878 by W. v. Leube—cases of general septicemia with concealed local infection undiscoverable even at necropsy, characterized by a fever that persists for weeks. Many of these recover completely, including cases in which the natural doubt as to whether they are of malarial or tubercular origin is settled in the usual way, against malarial by the inefficiency of quinin, and against tuberculosis by reason of recovery. J. M. Da Costa well described such cases in a paper on "Protracted Simple Continued Fever." † Some of the more serious forms have

* Abbott, A. C., "Effects of the Gaseous Products of Decomposition on the Health," etc. "Trans. of the Assoc. of Am. Physicians," vol. x., 1895.

† "Trans. of the Assoc. of Am. Physicians," vol. xi., 1896.

been traced after death by the aid of the bacteriological examination, to the streptococcus, staphylococcus, and even pneumococcus infection. Cases of prolonged fever, succeeding pneumonia and pleurisy, which subsequently recover may well be ascribed to any of these organisms.

Symptoms.—It can scarcely be said of the symptomatology of the milder forms of these fevers, to which reference is here intended, that it includes more than a mild *fever*, seldom reaching 103° F. (39.4° C.), with slight morning remission and evening rise, and the usual high-colored urine; it may be, with mild *gastro-intestinal derangement*, such as a slightly coated tongue, but no diarrhea, no lung complication, nothing essential but the mild fever. The latter is, however, rarely high, and there is occasionally enlargement of the spleen.

These fevers admit, moreover, of a certain classification, based on locality and perhaps on modifying local cause. This would be the case with the *thermic fever* of the South, described by John Guitéras, characterized by *wakefulness*, great *nervous excitement*, and *disordered muscular function*, but without eruption or other symptoms of typhoid fever, and lasting for several weeks. This, as suggested by Da Costa, is probably also the *ardent fever* of the older writers; in its severer form, the inflammatory fever, described by Copeland. On thermic fever, Guitéras tells me he has changed his views and is forced, in the light of modern studies, to ascribe it to some unknown infectious cause. To this, he says, he has been led by two facts, first, that he finds it farther north than he originally thought it occurred—his original studies were made at Key West—and, second, its occurrence in more than one member of a family.

Such, too, may be the “Asthenic Fever” of Murchison, and the “Starvation Fever,” described by Da Costa;* the “Atypical Continued Fever of Nashville,” described by Cain;† “Simple Continued Fever,” described by Baumgarten,‡ of St. Louis; the “Malta” or “Rock Fever,” already described; the “Innominate Fever” of Goodhart,§ who says in his paper, “There is too great a tendency to label all continued fevers by some definite name”; and the “Inexplicable Fever,” of Hale White.||

Diagnosis.—The cases are to be distinguished, above all, from irregular and mild forms of typhoid fever, similar forms of intermittent and remittent fever, miliary tuberculosis, the fever which sometimes attends chlorosis, hysteria at times, and some other nervous disorders. Da Costa emphasizes a feverish state caused by lithemia; another in rapidly advancing spinal sclerosis, which may be recognized by other distinctive signs, usually evident when sought for. In cases where there is enlargement of the spleen the resemblance to typhoid is closer, and the diagnosis may have to remain in doubt until settled by the Widal test or by time. The tubercle bacillus should always be sought for in doubtful cases; also the plasmodium of malaria.

Prognosis.—This is generally favorable, except in some of the severer cases ultimately traceable to true infection. Some cases of the so-called thermic fever, reported by Guitéras, died and came to autopsy without definite lesions being discovered.

Treatment.—The treatment of simple continued fever of longer dura-

* “Trans. of the College of Physicians of Philadelphia,” Third Series, vol. v., 1881.

§ “Guy’s Hospital Reports,” xxx., 1888.

|| “Brit. Med. Jour.,” vol. ii., 1886, p. 1096.

tion, as well as of the shorter forms, is symptomatic, and remedies for the relief of symptoms are for the most part alone indicated. With continued fever there is always a tendency to weakness, and supporting measures are indicated, including quinin, strychnin, and small doses of iron. Due attention to the bowels should be given, as the effect of constipation in keeping up fever is well known.

WEIL'S DISEASE.

SYNONYMS.—*Acute Febrile Jaundice; Bilious Typhoid.*

Definition.—An acute infectious disease, characterized by jaundice and fever, described by Weil in 1886.

Etiology.—The cause is as yet undetermined, but it affects males in preference to females, especially butchers, laborers, and brewers, and its subjects are from twenty-five to forty years of age. A few cases have occurred in this country, two having been reported from the Philadelphia Hospital by J. H. Musser and John Guitéras. Weiss considers that the symptoms and lesions most resemble the bilious typhoid described by Griesinger, while the latter has been claimed to be identical with the typhoid icterodes of Egypt.

It occurs commonly in the summer months, and nearly always in groups of cases. But for the last fact I should regard the disease as catarrhal jaundice.

Symptoms.—The disease sets in suddenly, after exposure to cold, as in a beer vault, most frequently with a *chill* and without prodrome. There is *fever*, with temperature of 102° to 104° F. (38.9° to 40° C.), *headache*, *muscular* and *joint pains*, and *epigastric pain*, which is characteristic. There is especially *tenderness* in the *calf muscles*. *Jaundice* promptly makes its appearance. The fever lasts usually from ten to fourteen days, and is characterized by decided remissions. The *liver* and *spleen* are both *enlarged*; the former may be tender. Associated with the jaundice are the usual *clay-colored stools* of obstructive jaundice. Beyond the epigastric pain, which may be hepatic in origin, *gastro-intestinal* symptoms are not marked, though the tongue is coated, and there may be vomiting and diarrhea. There may be dizziness, confusion of mind, and even delirium. The *urine* contains biliary coloring-matter; sometimes albumin with casts and even blood.

After a duration of from eight to fourteen days, convalescence sets in, usually slowly, and it may be prolonged.

Diagnosis.—The conditions with which Weil's disease might be for a time confounded are bilious remittent fever, acute yellow atrophy of the liver, phosphorus poisoning, and catarrhal jaundice. The first would be excluded by the absence of the plasmodium of malaria, while the mildness and favorable termination would exclude the second and third. Catarrhal jaundice is distinguished by the absence of fever, and of muscular, joint, and epigastric pain, which characterize Weil's disease.

Prognosis.—Recovery is usual, but a few autopsies have been made, with the discovery of no definite morbid anatomy. There is cloudy swelling and even fatty degeneration of the cells of the heart, liver, kidney, stomach, and intestines.

Treatment.—This is symptomatic.

MILIARY FEVER.

SYNONYMS.—*Febris miliaris; Sudor anglicus; Sweating Sickness; the Sweating Disease of Picardy; the English Sweat.*

Definition.—An infectious fever of unknown cause, characterized by profuse sweats and an eruption of miliary vesicles.

Historical.—The disease first appeared in London in an epidemic of extreme severity in the summer of 1486, a year characterized by very wet weather. There were other epidemics in 1517, 1518, and 1529. During the latter the disease passed on to the continent of Europe. There was not another epidemic until 1718, when there appeared “the sweating sickness” of Picardy, France, extending thence into Italy, Germany, Austria, and Belgium. Then there followed 194 epidemics up to 1879.

Etiology.—As to the specific cause nothing is known. It is not contagious nor inoculable, and not favored by crowding. Most epidemics occur in summer, fewest in the autumn; second in frequency is the spring; third, the winter. Moist, warm, and unchanging weather favors the disease. Contaminations of the soil, such as arise from neglected drains and collections of refuse, also contribute to its causation. More women are affected than men, and the vulnerable age seems to be between twenty and fifty years. The healthy and strong are as likely to be attacked as the weak, and the rich as well as the poor.

Morbid Anatomy.—No characteristic anatomical changes have been noted in miliary fever. The internal organs are generally hyperemic. The spleen is often enlarged. The most striking feature is the tendency to rapid decomposition, “beginning almost during life,” as has been said. The blood is thin and dark colored.

Symptoms.—After an *incubation* of two or three days the patient goes to bed apparently well, and wakes up in the night dripping with *sweat*. With this is a *sense of oppression*, and even *pain*, in the precordial region, *tenderness* and pain in the epigastrium, *palpitation*, *headache*, *dizziness*, and *muscular cramps*. The *temperature* is abnormally high, the *pulse* and *respirations* are frequent; there is even *dyspnea*, sometimes very violent. The perspiration continues, saturating the bed clothing and diffusing an unpleasant odor throughout the room.

On the third or fourth day, as a result of the profuse sweating, miliary *vesicles* make their appearance, at first so minute as to be scarcely visible, though they may be felt by passing the hand over the skin. As they become larger they are easily visible by their crystalline contents, which later become turbid and even milky. They appear first on the neck and breast, then over the back and extremities, less frequently on the abdomen and scalp. After two or three days they burst, dry up, and form crusts, which subsequently desquamate. With the appearance of the eruption the other symptoms disappear rather suddenly, but there is often noted a burning and prickling sensation of the skin. There is generally loss of appetite, sometimes nausea, seldom vomiting, scanty urine, and especially constipation.

The *duration* of the disease is usually from six to eight days, although it may be prolonged beyond this, the eruption being sometimes delayed to the seventh, tenth, and even fifteenth day. Relapses may occur. Sometimes the disease assumes an intermittent character.

Diagnosis.—This is not difficult. The prevalence of an epidemic, profuse sweating, and rash scarcely permit an error.

Prognosis.—The prognosis has varied greatly in different epidemics,

the mortality in some of the earlier reaching as much as 50 per cent., while in others none died. The average may be put down at from 8 to 9 per cent.

Treatment.—The treatment is mainly expectant and symptomatic. Simple febrifuges and acid drinks are indicated. Warm baths and sponging of the skin with warm water are soothing and comforting. The precordial distress and apnea may require anodynes, preferably subcutaneously administered. The sweating itself, if alarming, may be treated by hypodermic injections of atropin, 1-160 to 1-100 grains (0.00041 to 0.00066 gm.), p. r. n., or this drug may be given by the mouth in the same dose.

GLANDULAR FEVER.

SYNONYM.—*Driisen-Fieber*.

Definition.—An acute infectious fever of children, characterized by inflammation of the lymph glands of the neck, especially those back of the sterno-cleido-mastoid muscle.

History.—The disease is not a new one, as descriptions corresponding to acute adenitis of the glands affected have appeared from time to time, but the first systematic account seems to have been published by E. Pfeiffer in 1889 under the term *Driisen-Fieber*. In 1885-87 Filatoff, of Moscow, although less completely, described the same disease. Since then it has been studied by J. Park West, of Ohio, by Samuel McHamill and Albert E. Roussel, of Philadelphia, and by Donkin, Fischer and Dawson Williams, in England.

Etiology.—No responsible bacterium has been found. The disease may be epidemic, as was that which occurred in Bellaire, Ohio, described by West. It has been observed to prevail more commonly between the months of October and June in the winter season. The infection, whatever it may be, probably enters through the tonsils or the pharyngeal mucous membrane.

Morbid Anatomy.—This includes the enlargement of the glands, which forms so essential a part of the disease. The enlargement may involve not only the cervical glands referred to, but the axillary, inguinal, bronchial, and even the mesenteric. Thus, in West's report of 96 cases occurring between the ages of seven months and thirteen years, in three-fourths of them the post-cervical, inguinal, and axillary glands were involved, with the mesenteric in 37 cases. The liver and spleen were also enlarged, the former in 87 and the latter in 57 cases.

Symptoms.—The *period of incubation* lasts from five to eight days. The disease is characterized by sudden onset of stiffness with pain on moving the head. Along with this there is fever with a temperature of 101° to 103° F. (56° to 57° C.) with sometimes nausea and vomiting. The enlargement of the glands does not make its appearance until the second or third day, and may attain a size from that of a pea to a hen's egg, but rarely goes on to suppuration. The glands are tender to the touch, but there is not usually redness of the skin. There may also be some hyperemia of the tonsils, or pharyngitis. More rarely there is invasion of the tracheal and bronchial glands which may be the occasion of cough. The swelling persists from two to three weeks, although the fever does not last nearly so long.

Complications.—Among these which may be named as possible are hemorrhagic nephritis, post-pharyngeal abscess, and acute otitis media.

Diagnosis.—The disease is to be distinguished from the various forms of infectious sore throat found in scarlet fever and diphtheria which may cause a similar affection of the lymphatic glands.

Prognosis.—Favorable.

Treatment.—Active treatment is scarcely needed. The patient should be put to rest. Cold or warm applications may be made, whichever form is found more comfortable. An aperient, such as a dose of oil or calomel, may be desirable at the very beginning. West recommended small doses of the latter drug.

SECTION II.

DISEASES OF THE DIGESTIVE SYSTEM.

DISEASES OF THE MOUTH.

THE COATED TONGUE.

The *natural color* of the tongue at its anterior two-thirds is a pale red, on which the fungiform papillæ stand out as brighter red points. The epithelium covering the filiform papillæ, which are much more numerous and uniformly spread over the dorsal surface of the tongue, is thicker, and they are therefore less distinctly seen. As the base is approached, a grayish color is assumed on account of the greater thickness of the epithelium. At the base are seen the circumvallate papillæ, arranged in two rows of red circles. In the *furred* tongue the epithelium is abundant, though it is doubtful whether it is produced in increased quantity or is simply raised by hyperemic swelling of the papillæ. The "fur" is also contributed to by various forms of fungi. Too much stress should not be laid on the coated tongue. Some persons have a coated tongue and are perfectly healthy, while others have fair-looking tongues and are ailing seriously with those derangements which are commonly attended with coated tongue, especially gastro-intestinal disturbances. Food such as milk, and licorice and tobacco, also contribute to the coating of the tongue.

The *dry*, brown color of the tongue in low fevers is due to a drying of the rapidly exfoliating epithelium, admixed sometimes with mucus or saliva. The tongue may also be coated with dried food and sometimes with dried blood, due to capillary hemorrhage, which imparts to it a black color—the *black tongue* of certain malignant fevers. The tongue is sometimes *pale* and *anemic* in persons whose blood is poor and deficient in red blood-discs. The tongue in these cases is sometimes enlarged and flabby, while its edges are easily indented and marked by the teeth. A *bright red* or even a raw appearance of the tongue is met with in certain fevers, particularly in the early stages, when it may also be dry and glazed. It may be coated at the beginning, but later the epithelium desquamates freely and the whole surface may be red; or the fungiform papillæ may be hyperemic, swollen, and unusually distinct, constituting the "strawberry" tongue so characteristic of scarlet fever. The raw-beef appearance of the tongue is often seen toward the close of exhausting diseases, like tubercular consumption.

DERANGEMENT DUE TO DENTITION.

The most serious accident of dentition is what is known as the reflex convulsion, which will be considered among nervous affections. Other derangements of gastro-intestinal nature will be discussed under diarrhea.

These are not always reflex. They may be excited by irritation of the swallowed saliva, which is not only increased, but also altered in quality. Other anomalous conditions are observed in the natural order of eruption and certain markings on the teeth, ascribed to stomatitis.

The order of natural eruption of the *milk teeth* is well shown in the accompanying diagram. The first to appear are the lower central incisors (1, 1), at the age of from four to seven months, then a few weeks later the upper central incisors (2, 2), and next the upper lateral incisors (2a, 2a). Not until the beginning of the second year come the lower lateral incisors (3, 3), and almost simultaneously the four anterior molars (4, 4, 4, 4). In the second half of the second year come the four canines (5, 5, 5, 5), includ-

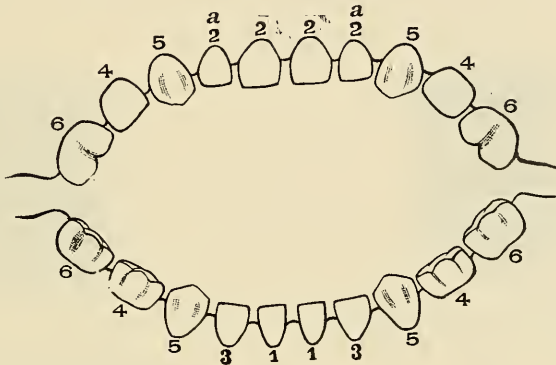

Fig. 26.—Diagram Showing Eruption of Milk Teeth.

- 1, 1. Between the fourth and seventh months, followed by a pause of three to nine weeks. 2, 2, 2 a, 2 a. Between the eighth and tenth months; pause of six to twelve weeks. 3, 3, 4, 4, 4, 4. Between the twelfth and fifteenth months; pause until eighteenth month. 5, 5, 5, 5. Between the eighteenth and twenty-fourth months; pause of two to three months. 6, 6, 6, 6. Between the twentieth and thirtieth months—(from Louis Starr, slightly modified).

ing the two "eye," two "stomach" teeth; and finally the four posterior molars (6, 6, 6, 6); so that by the end of the second or beginning of the third year the first dentition is completed. The milk teeth begin to be replaced by the *permanent* set in the *fifth* or *sixth* year. Before any of the milk teeth are shed the first grinders of the second set are fully developed. Hence they are called the six-year molars. About twelve years are consumed in the cutting of the remaining teeth, but the variations of the date of appearance of each tooth are so great that it is not worth while to attempt to name the dates.

In some children (usually the rachitic, the feeble, and badly nourished) the appearance of the milk teeth is greatly delayed—the lower incisors do not appear until the eleventh or twelfth month; but the completion of dentition is not much delayed thereby, though under these circumstances dentition is sometimes not completed until the end of the third year. In others they appear earlier,—in the third or fourth month,—and occasionally children are born with them. It has always seemed to me that the first appearance of the teeth is more apt to be delayed in blondes and anticipated in brunettes.

The diet of children during dentition should be very carefully watched, as the whole *gastro-intestinal* tract is sensitive and irritable and readily thrown into inflammation. The mouth is tender, the saliva flows freely, and the child is disposed to bite on anything. The term *tooth rash*

is applied to certain eczematous eruptions that sometimes appear during teething. Their relation to teething is not certainly established.

Very rarely a purulent conjunctivitis makes its appearance during the eruption of the upper canines or "eye teeth," which is ascribed to dentition and explained by contiguous extension of inflammation through the antrum of Highmore and the lachrymo-nasal duct.

Certain markings are often found on the teeth as a consequence of stomatitis. They include pittings and linear depressions, the result of defects in the development of the enamel. Extreme degrees produce a honey-combed appearance. These, as well as the syphilitic teeth of children, have been studied by Jonathan Hutchinson, and are not to be confounded with the latter. (See Figs. 27 and 28.) The "honeycomb" changes are most

Fig. 27.—Thin-edged and Broken Teeth, not Syphilitic, from a Woman, aged Twenty.

The notches in the upper teeth differ markedly from those shown in Fig. 19. In these they result not so much from the softness and original malformation of the teeth as from their preternatural thinness and brittleness. Near the edges of the lower set a horizontal line of notches is seen to extend—(after Hutchinson).

Fig. 28.—The Permanent Front Teeth of a Boy, aged Fifteen, who had Taken Much Mercury in Infancy.

The teeth are all of yellow color, somewhat pitted in their surfaces, and very thickly coated with tartar. Near the edges of the lower set a horizontal line extends similar to that in Fig. 27—(after Hutchinson).

conspicuous in the permanent teeth, of which the first molars, according to Hutchinson, are the test teeth, though he says the incisors are almost as constantly pitted, eroded, and discolored, often showing a transverse line which crosses all the teeth at the same level. These transverse furrows are also ascribed by Magitot to infantile convulsions or other severe illness in early life.

STOMATITIS.

SIMPLE ACUTE CATARRHAL STOMATITIS.

Definition and Etiology.—A simple erythematous inflammation of the mouth, commonly caused by diffuse chemical or mechanical irritants, such as overheated food (very hot drinks), acids, alkalies, stimulating condiments (red pepper, horse-radish, and the like), by excessive smoking and use of alcohol. It occurs in adults and children from the action of such causes, independently of the state of health, but is prolonged when its subjects are unhealthy and ill-nourished. Dentition is also a cause, while stomatitis may accompany also indigestion and the acute fevers.

Symptoms.—The mucous membrane is reddened wherever the irritation has reached, but the redness may be greater in certain situations, as on the tongue, gums, lips, and cheeks. There may be at the very beginning dryness, but it is soon followed by increased secretion and slight swelling. There is always discomfort that may amount to pain, which is increased by the introduction of food and its mastication. A corresponding slight febrile movement may be present.

Treatment.—The treatment of simple catarrhal stomatitis will be considered in connection with that of the other forms of stomatitis to be described.

APHTHOUS STOMATITIS.

SYNONYMS.—*Vesicular or Herpetic Stomatitis; Aphtha; Canker; Follicular Stomatitis.*

Description and Symptoms.—Some confusion attends the use of this term. The term “aphtha” from the Greek means “an eruption.” Aphthous stomatitis is sometimes confounded with thrush, but it is not commonly regarded as a parasitic disease, as is thrush, nor as a follicular disease. Some speak of it as herpetic or vesicular. The little grayish-white spots which characterize it consist primarily of an exudate of fibrin and wandered-out leukocytes, which pervades the superficial layer of the mucous membrane and is at first covered by epithelium. Hence, an attempt to remove the spots by forceps is futile and followed by bleeding. They are small, round, usually not more than a few millimeters in diameter, and surrounded by a red areola of hyperemia. They are most common on the cheeks and lips, especially in the gingival groove at the base of the latter. They also occur on the tip and edges of the tongue, more rarely on the dorsum. The epithelium dies and desquamates, leaving a superficial ulcer, which under favorable circumstances heals up rapidly. Under more unfavorable conditions the ulcer grows deeper and becomes more painful, constituting one of the forms of ulcerative stomatitis. Young children are especially subject to it, but it is common also in adults, especially at times of temporary physical depression, as in women during menstruation, pregnancy, and lactation.

The aphthæ are commonly associated with a variable amount of simple stomatitis, with increased secretion of saliva, a slight “heaviness” of the breath, but without fetor. There is commonly a stinging sensation, especially when brought in contact with food, and even when the tongue and lips are moved in speaking. There is often some constitutional disturbance, including fever.

A similar condition is *Riga's disease*, in which a pearly-colored membrane with induration forms on the frenum of the tongue. It occurs in Southern Italy in unhealthy and cachectic children about the time of eruption of the *temporary* teeth, and may be epidemic.

THRUSH—MYCOTIC STOMATITIS.

SYNONYMS.—*Parasitic Stomatitis; Soor; Miguet.*

Definition.—Thrush is characterized by grayish-white deposits in the buccal and pharyngeal mucous membranes, due to the development and inter-

penetration of the epithelium by a fungus variously known as *oidium albicans* or *saccharomyces albicans*. It is a variety of yeast fungus made up of branching filaments, at the ends of which oval cells develop. It does not grow on the normal mucous membrane. It forms minute white and yellowish spots scattered copiously over the palate, tongue, and cheeks, uniting at times to form larger areas. It may extend into the esophagus and even larynx. In severe cases the entire buccal mucous membrane may be covered. Stenoses of the esophagus have resulted from its accumulation. The little areas are commonly surrounded by an inflammatory areola, and may be scraped off, though with some difficulty, leaving the mucous membrane sometimes intact and sometimes slightly excoriated and bleeding.

Thrush is chiefly a disease of nursing children, and is favored by feeble and dyscrasic states and by the want of cleanliness, especially in the care of nursing-bottles and nipples when children are brought up on the bottle. It may be associated with any of the diseases of children or may occur independent of them. It also occurs in adults after long illness or in dyscrasic diseases like diabetes mellitus and tubercular consumption. Thrush is often unattended by other symptoms, though the mouth may be sensitive and nursing painful. There should be no difficulty in diagnosis. In thrush the spots are smaller than in aphthous stomatitis, and the microscope at once removes all doubt. The mouth is dry as contrasted with the moist mouth of aphthous sore mouth, where there is free salivation.

Other Varieties of Stomatitis Due to Fungi.—The mouth is a favorite seat for the development of fungi, because of the warmth, moisture, and organic matters constantly present. Though ordinarily harmless, in certain states of the system they may play an important rôle in producing ulcerative stomatitis, as already suggested. Especially worthy of mention are the diplococcus of Fränkel and the pneumonia bacillus of Friedländer; also the delicate, thread-like *leptothrix buccalis*, thought to exert a significant part in the production of caries.

ULCERATIVE STOMATITIS.

SYNONYMS.—*Stomacace*; *Fetid Stomatitis*; *Putrid Sore Mouth*.

Definition.—This is a much more serious disease of the mucous membrane of the mouth, attended with necrosis of the mucous membrane and resulting ulceration.

Etiology.—Any one of the above named diseases may become ulcerative. It may begin as an aphthous stomatitis, taking on the more serious form in the ill fed and badly cared for, or in those who are indifferent in the care of their mouths. In these, an abrasion or laceration due to any cause, as the tooth-brush or a sharp carious tooth, may be the initial lesion. An ulcer may begin, too, in a herpetic vesicle, which, on rupturing, leaves a raw surface that may remain isolated or unite with others. It is a frequent attendant of mercurialization—*mercurial stomatitis*. The ulcer sometimes starts in the mucous follicles of the mouth. In all these cases the stomatitis is probably the result of infection by some organism as yet not isolated; it may be the omnipresent streptococcus or staphylococcus, to which the sound mucous membrane in health is invulnerable, but which finds a nidus in the abrasions and conditions referred to.

Symptoms.—The ulcers may occur in any of the situations already named, the lips, cheeks, and, more rarely, the tongue. They vary in size, but are usually of an ashen-gray color, with red areolæ, and often exhibit a tendency to bleed.

Additional symptoms are profuse *secretion*, exquisite *pain* and *tenderness* in the ulcers and vicinity, a *fetid odor* of the breath, which sometimes pervades the apartment. The *gums* become spongy and, in extreme cases, the *teeth* are loosened. There are proportionate constitutional disturbances, *fever*, and often *swelling* of the glands at the angle of the jaw.

With reference to *mercurial stomatitis*, or mercurial ptyalism, previously mentioned, this condition is due to mercury administered as a medicine or absorbed in the course of occupations in which mercury is handled. Acquired in the former way, ptyalism, at the present day, is usually accidental rather than designed, in persons exhibiting a peculiar susceptibility. In such persons even fractional doses frequently repeated sometimes produce salivation in a day or two. The symptom first observed is usually *fetor of the breath*, unless the patient be closely watched during the administration of the drug, when tenderness may be ascertained on closing the jaws with some force. Examination will then discover a swelling of the gums about the teeth. Or a metallic taste may make its appearance as the first symptom. To these symptoms *salivation* is soon added, and becomes more or less profuse according to the severity of the poisoning. In severe cases, the entire mucous membrane of the mouth becomes swollen, as does also the tongue. In such cases, also, ulceration and loosening of the teeth take place. This form of stomatitis was not infrequent in the older treatment of syphilis, which used to fill a hospital ward with a sickening fetor at once recognizable. Actual loss of teeth was, perhaps, less common than is supposed even in those days, yet necrosis of the jaw has, in rare instances, resulted.

Syphilitic stomatitis is also ulcerative, and the ulcers exhibit the same gray color. But the syphilitic ulcers are found in the throat as well as on the gums and cheeks and in the angles of the mouth. They are less disposed to bleed than those of non-specific ulcerative stomatitis, and are really less angry-looking, but penetrate to greater depth.

Parrot's ulceration is a form of ulceration occurring in new-born children, consisting of small, symmetrically placed ulcers on the hard palate on both sides of the median line. *Bednar's aphthæ*, two symmetrically placed ulcers, also occurring on the hard palate on either side of the mesial line near the velum, are similar, though not regarded as identical. This variety is thought to be traumatic in origin, at least in most cases, either the result of pressure of an artificial nipple against the hard palate, or of undue pressure in washing the mouth. Both are described as usually harmless, but in poorly cared for children may be converted into extensive and deep ulcers. Especially is this the case in the form described by Parrot, which may invade the adjacent bone.

Diagnosis.—*Scurvy*, though a general disease, happily rare of late, is characterized by local symptoms about the mouth, which include ulceration. There are swelling and bleeding of the gums, which rise up around the teeth. The latter become loosened and ulceration may extend even to the lips and cheeks. The tongue and fauces are not invaded by ulcers, but are subject to ecchymoses. Salivation and fetor of the breath are also symptoms, though less decided than in severe ulcerative stomatitis. On the other

hand, in extreme cases deep-seated gangrenous processes are met. Along with these are, however, the general symptoms of scurvy, by which it is commonly easily recognized.

Treatment of Different Forms of Stomatitis.—*Prophylaxis* is exceedingly important in averting these various mouth affections. In the case of infants the mouth should be washed out with antiseptics after each nursing. Nothing is better than a saturated solution of chlorate of potash, boric acid, or sulphate of sodium, 15 grains to the ounce (1 gm. to 30 c. c.) of water. So, too, the adult should cleanse the teeth after each meal. Listerin, diluted with twice as much water, is an elegant and efficient wash. Equal parts of phenol-sodique and water are also efficient. Compounds similar to listerin and much cheaper may be made up. The following is one known as *spiritus thymol comp.* in the Dispensary of the University of Pennsylvania :

R	Acid. benzoic.,	gr. 64
	Pulv. sodii borat.,	gr. 64
	Acid. borac.,	gr. 128
	Thymol,	gr. 20
	Eucalyptol,	m 5
	Ol. gaultheriæ,	m 5
	Ol. menthæ pip.,	m 3
	Ol. thymi,	m 1
	Spt. vini rect.,	ʒ iij
	Aquæ destillat.,	q. s. ad	ʒ xvj
	Mix and filter, and color with fluid extract of hydrastis.								

Any of these substances may be used on the tooth-brush as a simple mouth-wash. The tincture of myrrh, a teaspoonful to four ounces of water, should not be forgotten, and though less agreeable, carbolic acid may be used in the same proportion. Permanganate of potassium in the shape of Condy's fluid, a teaspoonful to a tumbler of water, is an excellent wash.

If stomatitis is established, cleanliness is no less important and may be secured by the same antiseptic measures. In addition, the mouths of children may be treated with honey and borax,—the *mel boracis* of the pharmacopœia,—to which alum may be added. Alum itself is an admirable astringent, too much overlooked of late. A moderately strong solution may be made, 30 grains (2 gm.) to the ounce (30 c. c.), or the powdered alum itself may be applied to the aphthous sore mouth.

For the painful aphthous ulcers of adults there is really nothing so efficient as touching with a pointed piece of nitrate of silver. A single application will often suffice, but when healing does not follow, it may be made daily. A very good application also is a solution of equal parts of tincture of the chlorid of iron and glycerin, applied to the ulcers with a brush. Chlorate of potassium in saturated solution is also a very good mouth-wash, to eight ounces (240 c. c.) of which 1-2 a fluidram to a dram (2 c. c. to 4 c. c.) of tincture of the chlorid of iron may be added.

General treatment should not be overlooked. Many persons the subject of stomatitis are much run down, and require iron, quinin, and strychnin, with nutritious food, to build them up. Attention should also be paid to the bowels.

The management of mercurial stomatitis is in no way different from that of other forms. Astringents and disinfectants are especially indicated. It goes without saying that the administration of the drug itself must cease.

CANCERUM ORIS.

SYNONYMS.—*Gangrenous Stomatitis; Water Cancer; Noma.*

Definition.—A rare disease, characterized by hard infiltration of the cheek near the angle of the mouth, succeeded by rapid gangrene proceeding outward and inward from the central focus until the cheek is perforated, and the gangrenous mass separates. It may start in the gums and produce necrosis of the jaws. It is confined to one side of the face.

Etiology.—A parasitic origin seems likely, but has not been proven. It occurs in girls and boys from two to five years old, affecting more of the former than of the latter. Rarely it affects adults. It is usually confined to those badly fed and surrounded by unsanitary conditions, especially when convalescent from infectious fevers, one-half of all cases having arisen during convalescence from measles, scarlet and typhoid fevers. It may, however, be primary. Damp regions seem to favor it.

Symptoms.—Its approach is insidious, and it is generally well advanced when discovered. In its extreme severity it may involve the bones of both jaws, the eyelids, and ears; but in its mildest form its results are limited to perforation of the cheek. The dead tissue comes away in dark, offensive shreds.

The constitutional disturbance corresponds to the degree of local involvement, there being high *fever*, reaching often 104° F. (40° C.), with frequent pulse and rapid exhaustion. The adjacent lymphatics are swollen. Inhalation-pneumonia of corresponding virulence often succeeds, while intense irritation of the stomach and bowels follows the swallowing of the ichorous discharge.

Diagnosis.—Noma has rarely to be discriminated from anything else. *Malignant pustule* is less local in its invasion, furnishes the history of contagion, is even more severe in its constitutional effects, and exhibits the appropriate bacillus. Very bad cases of *ulcerative stomatitis* sometimes suggest cancrum oris, but the devastation is not so rapid, nor is there such a tendency to invasion of the external integument.

Prognosis.—This is almost invariably fatal at the end of three or four days, only the promptest and most energetic treatment occasionally saving life.

Treatment.—This consists in the prompt use of the glowing cauterly, Paquelin's being sufficient. In its absence cauterization with strong nitric acid may be substituted. Local antiseptic treatment should be carried out in the most thorough manner, syringing with antiseptics being most efficient, while stimulating and nourishing food should be administered.

GLOSSITIS.

Parenchymatous glossitis, or inflammation of the substance of the tongue, is a rare disease, but occurs as the result of violent injury to the organ, as by accidental biting or poisonous stings. Apparently idiopathic inflammations are probably the result of concealed causes of the kind described.

Symptoms.—The tongue is enormously *swollen* and *painful*, and sometimes extruded from the mouth. There is great difficulty in speech, masti-

cation, and deglutition, and in extreme degrees these are scarcely possible. The discomfort is almost indescribable, and there may even be *obstruction to breathing*. If exposed, the tongue becomes dry and fissured. There may be suppuration. There is *fever* corresponding to the amount of local disturbance.

Treatment.—This consists in the constant application of ice, of frequent antiseptic cleansing of the mouth, and sometimes of scarification. Evidence of the presence of pus must be followed by the prompt use of the lancet.

Glossitis desiccans is a more chronic affection of the tongue, characterized by deep fissures and indentations, giving it an uneven, ragged appearance. Associated therewith are excoriations and occasionally superficial ulcers. Severe pain is caused by contact of acids and even the usual food. Its etiology is not known, but it is sometimes associated with gastro-intestinal derangements.

Treatment.—This should be directed to the cause, if it can be discovered. Washes of chlorate of potash should be employed, and if there are ulcers, they should be touched with solid silver nitrate.

ECZEMA OF THE TONGUE.

SYNONYM.—*Geographical Tongue*.

Definition and Symptoms.—A localized superficial hyperplasia and desquamation of the epithelium of the tongue, sometimes associated with similar spots in the cheeks and lips. The central parts tend to heal, while the periphery spreads, producing circinate patches. The patches fuse and extensive areas are formed, bounded with sinuous outlines. The appearance has been compared to that of a map—*lingua geographica*. The condition is chronic, sometimes lasts years, but does not usually cause inconvenience save by the itching and burning it occasions and the apprehension of more serious disease. It is occasionally mistaken for syphilitic disease. It is best treated by solutions of nitrate of silver, which relieves the itching. Weak solutions of iodine may be useful, applied with a brush.

LEUKOPLAKIA BUCCALIS.

SYNONYMS.—*Ichthyosis lingualis*; *Buccal Psoriasis*; *Keratitis mucosa oris*; *Smoker's Tongue*.

Definition and Symptoms.—A condition in which there are intense white spots on the mucous membrane of the mouth and tongue, consisting in thickened epidermis. They are also sometimes mistaken for syphilitic plaques. The spots on the sides of the tongue are often notched, giving them a scar-like appearance. Those on the inner surface of the cheek are simply flat, tabular swellings. They disappear, to be replaced by others; they rarely give rise to inconvenience. Sometimes those on the sides of the tongue become ulcerated, when they are painful if brought into contact with irritants. They have been ascribed to smoking, and, though acknowledged to be of non-syphilitic nature, it is said they occur in those who have had syphilis. They occur in adults of both sexes. They sometimes become papillomatous, and are said to have been the starting-point of true epithelioma, as often as once in every three cases.

Treatment.—They are harmless and require no treatment unless ulcerated, when the usual stimulating measures for healing ulcers may be applied. Hot and irritating substances should be kept from the mouth, and smoking interdicted. Should the spots develop into papillomatous or epitheliomatous structures, they should be operated on by the surgeon.

MUCOUS PATCHES.

The true mucous patches or flat condylomata are opaque, white, flat, tabular swellings on the lips, tonsils, tongue, and arches of the palate, and especially at the border-line between skin and mucous membrane. They consist of an irregular imbricated thickening of the superficial layers of the skin; the cells are swollen and papillæ of the mucous corium hypertrophied.

Treatment.—The treatment of the mucous patches of syphilis is that of syphilis constitutionally, and locally by applications of nitrate of silver.

DISEASES OF THE SALIVARY GLANDS.

FUNCTIONAL DERANGEMENTS.

Ptyalism, or *excessive secretion* of saliva, is a symptom of mercurial poisoning, also of poisoning by gold, copper, and iodine. Some persons are very susceptible to iodine, so that a few grains of iodide of potassium will cause intense salivation, with pain in the salivary glands. Vegetable substances producing the same effect are jaborandi, muscarin, tobacco. Indeed, almost anything which admits of constant chewing without solution or destruction produces salivation. This is the mechanism of the various agents used in the disgusting practice of chewing gum.

Xerostomia, or *dry mouth*, is the opposite condition of arrest of salivary and buccal secretion, not due to fever,—a rare condition, first described by Jonathan Hutchison. As a consequence the tongue and mucous membrane are red, dry, and shining. It is more common in women, in whom it follows intense emotion, such as fright, or is associated with hysteria and hypochondriasis. It is probably a neurosis, the result of some cause operating on the center which controls the secretion of saliva and other buccal glands.

Treatment.—The treatment of ptyalism and xerostomia is that of the conditions producing them.

INFLAMMATION OF THE SALIVARY GLANDS.

ACUTE PAROTITIS, OR PAROTID BUBO.—Apart from mumps, or specific parotitis, considered under infectious diseases, in which any or all of the salivary glands may be involved, the parotid is subject to inflammation from the following causes:

1. In the course of infectious diseases, especially typhoid fever, but also scarlet fever, typhus fever, pneumonia, pyæmia, and secondary syphilis.

2. In connection with diseases or injury of organs in the abdomen or pelvis, including the alimentary canal, urinary tract, abdominal wall, peritoneum, pelvic cellular tissue, or genital organs—a very interesting group of cases, which have been especially studied by Stephen Paget. Sometimes simple transient irritation, such as a blow on the testis or the introduction of a pessary, may produce it.

3. In association with facial neuritis. A fatal case, apparently of such origin, has been reported by Gowers.

In (1) and (2) septic infection is doubtless the cause of the inflammation, which is often intense, going on to suppuration in more than one-half of the cases. Its possible origin through the duct of Steno was considered in treating typhoid fever. In (3) there is probably some vasomotor disturbance which is responsible.

Treatment.—This should consist, at first, in attempts to allay the inflammation by leeches and the application of cold, especially ice. Failing in this, fomentations should be applied, while the lancet should be used at the first indication of suppuration.

CHRONIC PAROTITIS sometimes succeeds on acute inflammation, as that of mumps; also on mercurialization or lead poisoning, syphilis, and Bright's disease. Sometimes no cause is discoverable. It may be painful or tender or painless. It may be treated by ointments reputed to promote absorption—ointments of iodine and mercury.

ANGINA LUDOVICI.

SYNONYMS.—*Ludwig's Angina; Cellulitis of the Neck; Cynanche Gangrænosa.*

Definition and Symptoms.—An inflammation of the floor of the mouth, beginning in the submaxillary gland; it occurs first on one side as a secondary inflammation in the specific fevers, including, especially, typhoid, diphtheria, and scarlet fever, but it may also be primary. It is probably a streptococcus infection. It spreads rapidly over the floor of the mouth and the anterior surface of the throat, sometimes invading the glottis by edema, and sometimes terminating in sloughing of the soft parts—*cynanche gangrænosa*. Or it may go on to abscess pointing externally or internally. More rarely, resolution takes place.

Further symptoms are *swelling* and extreme *pain*, first in the neighborhood of the submaxillary gland, increased by chewing, swallowing, and talking. The swelling may produce compression of the larynx, with resulting dyspnea, which is suffocative if the glottis becomes involved. Constitutional infection may take place, with its grave array of symptoms and fatal termination. There may be remissions and exacerbations.

Treatment.—This should consist in energetic measures calculated to combat the inflammation, such as the use of ice and leeching, but very early surgical interference is likely to be called for.

DISEASES OF THE TONSILS AND PHARYNX.

QUINSY.

SYNONYMS.—*Acute Parenchymatous Tonsillitis; Phlegmonous Tonsillitis; Tonsillar Abscess; Cyanche tonsillaris.*

Definition.—An acute inflammation of the substance of the tonsil.

Etiology.—Quinsy is a disease of later youth and adults, being rarely found in children under ten years of age, and not often in adults over forty. Some persons are much disposed to tonsillitis, scarcely a season passing for them without an attack, and sometimes more than one attack. In such, almost every cold terminates in acute tonsillitis. Others, after a single attack, never have another, and others still are entirely exempt. Tonsillitis is probably always the result of infection. Exposure to wet and cold certainly often precedes it. Persons predisposed to tonsillitis are often the subject of chronically enlarged tonsils. Overdistention of the follicles with inspissated secretion may also be a cause of inflammation and suppuration.

Morbid Anatomy.—The tonsil, more frequently on one side, sometimes on both, or on two sides in succession, becomes rapidly enlarged, red, and painful. It is at first hard and resistant and very tender to the touch, but, if suppuration takes place, it gradually softens until rupture happens or the abscess is opened with the knife. The lymphoid parenchyma of the gland becomes more and more distended with leukocytes until the entire gland, or a large part of it, is converted into a *pus* sac. When both tonsils are involved, the throat is often almost closed by the swelling.

Symptoms.—The superadded symptoms are *pain* and *difficulty of deglutition*, attended by increased pain, which is often agonizing. The jaws are stiff and the mouth cannot be opened above half an inch without extreme suffering. The difficulty in opening the mouth is increased by the swelling of the external glands of the neck. The pain is not confined to the interior, but extends to the neighborhood of the angle of the jaw, the front of the ear, and the floor of the mouth. The voice is greatly altered, having the characteristic nasal drawl, and the diagnosis can sometimes be made from the altered speech alone. There is increased salivation, and the saliva dribbles from the mouth because of the pain in swallowing it, while it also often becomes fetid. Respiration may be seriously interfered with.

There is high *fever*, the temperature reaching 104° and 105° F. (40° to 40.5° C.), while the *pulse* is full, bounding, and frequent, 110 to 130 a minute. The *face* is *anxious* and tells the tale of suffering. From two to six days are occupied in the completion of the process, at the end of which time the abscess begins to point, usually toward the interior of the mouth, when relief is obtained by spontaneous rupture. But more fortunate is the patient who is relieved early by the lancet. Sometimes the abscess points toward the pharynx. The importance of relief at the earliest possible date is emphasized by the fact that death by suffocation has resulted from the discharge of a quinsy passing into the larynx.

Prognosis.—Apart from the rare accident just referred to, the prognosis is favorable, though it must be mentioned also that death from suffo-

cation has occurred where the obstruction by double-sided quinsy was so great as to prevent respiration.

Treatment.—The physician who suggests a successful plan for "backing" of a quinsy will well deserve the thanks of untold sufferers. As yet such measure remains hidden. Free scarification is sometimes useful in shortening an attack, but it is painful, unreliable, and sometimes difficult to do thoroughly. If deferred until about the third day, it will often co-operate with the advancing suppuration and favor an early rupture. Other applications to the tonsils are of doubtful efficacy, though some relief from pain may be secured by painting the surface with a 10 per cent. solution of cocain. Painting with a 40-grain (2.6 gm.) solution of nitrate of silver, after thorough cleansing with a cotton swab, is recommended. Parenchymatous injections of carbolic acid are also advised by Kramer,* with a view to prevent abscess formation. The part is made completely anesthetic by cocain, a sterilized needle attached to a hypodermic syringe gently introduced into the gland, and through this are injected from 7 to 15 minims (0.5 to 1 c. c.) of a two- to three-per cent. solution of carbolic acid. This may be repeated once or twice a day.

Cold, so soothing in other forms of sore throat, often occasions more discomfort than relief. Then poultices and fomentations to the exterior of the throat are apt to be more soothing. And since little can be done to prevent suppuration, these measures are indicated to hasten it. The tonsil should be frequently felt with the finger, and as soon as there is evidence of suppuration, the lancet should be used. A curved bistoury, guarded with adhesive plaster almost to the end, is best. The incision should be made from above downward, parallel to the anterior half-arch. If danger of suffocation is imminent, the tonsil must be shaved off, while extreme cases may even demand tracheotomy.

FOLLICULAR TONSILLITIS.

SYNONYMS.—*Angina follicularis*; *Lacunar Tonsillitis*.

Definition and Symptoms.—A form of catarrhal inflammation of one or both tonsils, associated with whitish-yellow spots corresponding in situation with the lacunæ or follicles of the gland. The inflammation may rarely extend to the soft palate, but the white or yellow spots are the most conspicuous feature. In a day or two they drop out or may be pressed out, when they are found composed of epithelial cells, pus-corpuscles, bacteria, and débris, to which are sometimes added cholesterin plates and fat-crystals. If let alone, they may disappear rather suddenly, so that if seen one day they may be gone the next, having evidently disintegrated and dropped out spontaneously. More rarely the little follicle is converted into a small abscess.

The disease occurs in children and young adults, and is one of the affections sometimes mistaken for diphtheria, and is also called diphtheritic sore throat. It is, however, something very different. It is a much less serious disease, of shorter duration, and patients never die of it. It is, however, probably infectious in origin, caused by a germ other than the diph-

* "Anales del Circulo Medico Argentino," October 15, 1897.

theritic, perhaps the streptococcus or staphylococcus. There is often very decided fever.

Treatment.—The treatment of this form of tonsillitis is definite and easily carried out. In the first place, cold should be applied to the neck by cloths wrung out in cold water or by ice, which is conveniently applied in little muslin bags made to fit under the angle of the jaw and held in place by a bandage. Then iron and chlorate of potassium are, without doubt, the remedies *par excellence*, and to these may be added the bichlorid of mercury, if diphtheria is not certainly eliminated from the diagnosis. The antiseptic measures recommended for the throat in diphtheria are not necessary. The disease is an acute one and subsides rapidly without any of these applications. There is, however, a very decided drain on the strength of the patients thus affected, however short the duration of the illness. Hence, quinin and iron should be given and continued during convalescence.

CHRONIC TONSILLITIS AND HYPERTROPHY OF THE ADENOID TISSUE OF THE PHARYNX.

SYNONYMS.—*Chronic Enlargement of the Tonsils; Chronic Naso-pharyngeal Obstruction; Mouth Breathing; Aprozexia.*

Definition.—A chronic inflammatory enlargement of the tonsils or of the adenoid tissue of the pharynx, of the lingual tonsil, or of two or more of these structures.

Etiology.—The most frequent cause is repeated attacks of acute tonsillitis and of inflammatory processes associated with hyperemia of the tonsils and vicinity, including scarlet fever and diphtheria, while chronic illness, especially skin affections, bad hygienic surroundings, and insufficient and unsuitable food favor it. It is, therefore, naturally more common in children, in whom it is also sometimes congenital, but it is found usually at the ages of five to fifteen years, and rather more frequently in boys. Adenoid overgrowths of the pharynx and lingual tonsil are due to the same causes.

Morbid Anatomy.—The enlargement of the tonsils is a true lymphoid overgrowth, usually symmetrical. The occasional presence of fibrous stroma produces a harder and smoother tissue. The lumen of the throat is variously encroached upon, sometimes almost closed. The pharyngeal adenoid overgrowths vary in extent from a slight increase in natural unevenness to the formation of actual sessile and pedunculated tumors. The same is true of the tonsillar structures at the base of the tongue, which may encroach upon the glottis.

Symptoms.—Simple chronic enlargement of the tonsils may give rise to no symptoms except when the seat of further enlargement due to acute inflammation. Then *obstructed breathing* is immediate, while it is also a permanent symptom in the more advanced forms. It is proportionally contributed to by overgrowth in any of the situations named. The result is *mouth breathing*, which is, perhaps, earlier necessitated by pharyngeal than tonsillar overgrowth, while it may be due altogether to the former, the latter being entirely absent. Tonsillar obstruction is, however, more frequent. The effects are usually first apparent at night, when the child is found to be

breathing, more or less noisily, with its mouth open and head thrown back. *Disturbed rest* is an inevitable consequence, the patient often waking up with a start, again relapsing into sleep, or continuing permanently aroused because of the dyspnea, which often only gradually passes away.

As the conditions persist a *changed expression of countenance* is gradually acquired. The face becomes apathetic, staring, and vacant, an appearance chiefly produced by the constantly open mouth. To this may succeed actual mental failure and even stupidity, with sullenness and general bad temper. Further changes in expression are occasioned by contraction of the nostrils and projection of the upper jaw and lip. If the condition is still unrelieved, *deformities of the chest* make their appearance, of which the most conspicuous is the well-known *chicken breast*. In it the upper sternum projects, the manubrio-gladiolar articulation being most prominent, while the lower part is depressed, causing a groove at the gladiolo-xiphoid articulation. There is a cup-like depression of the lower costal cartilages and a horizontal circular depression (Harrison's groove) in the thorax corresponding to the attachment of the diaphragm. The ribs are separated from each other anteriorly and closely approximate posteriorly, especially in the lower thorax. Posteriorly the lower angle of the scapula projects. This is the result of the act of breathing, a study of which during sleep will recognize the retraction of the lower part of the thorax during inspiration, caused by the action of the diaphragm.

Another form of chest is the *round or barrel chest*, such as is commonly associated with chronic asthma, due to the same cause. Still another said to be caused by mouth breathing is the *funnel breast*, or *Trichterbrust* of the Germans, in which there is a deep central depression at the epigastrium.

Other symptoms are an *altered nasal voice* in which the letters *m* and *n* are especially badly articulated, the *special senses* of smell, taste, and hearing are deranged, the breath is fetid from decaying secretion, the appetite is impaired, and with it the nutrition of the body. A gradual mental as well as physical deterioration takes place.

Among the symptoms ascribed to this condition are *habit chorea* and *stuttering*. The former will be considered in a later section. There is an almost *constant cough*, which is well termed "throat cough," since it is due to irritation of the respiratory passages by the throat outgrowths and the secretion caused by them. This secretion is generally swallowed by children, but is in part expectorated by adults by the aid of troublesome hawking and coughing, which is stimulated by a sensation as of "something in the throat" or larynx which demands clearing. The absence of discharge from the nose in both children and adults is surprisingly frequent, sometimes misleading the physician as to the true cause.

Defective hearing is another symptom due to obstruction of the Eustachian tube by encroachment of the adenoid growths, or by inflammations, or to retraction of the drum. *Impaired taste* and *smell* are due to involvement of the gustatory papillæ and the terminal distribution of the olfactory nerve. *Extreme fetor* of the breath is sometimes present, due to retention of cheesy masses in the crypts of the tonsils. These are often easily visible, are sometimes expectorated, and can usually be expressed. The odor of these masses when compressed between the fingers is indescribably disagreeable. Sometimes they are found in the tonsils of persons not otherwise affected. The very great susceptibility of the subjects of this disease to "cold" is constantly adding aggravation to the symptoms described.

Diagnosis.—This is not usually delayed at the present day, since the more thorough examination of the throat and nose has become common—thanks to the throat and nose specialists. Most important is it to remember that there may be no tonsillar disease, and all the symptoms may be due to advanced adenoid growths of the pharynx. Digital examination by the finger affords the most ready and accurate means of diagnosis. Especially thorough must be the examination behind the pillars of the fauces. In children this can only be done with the finger, but in adults the half-arches may be drawn forward, while the laryngeal mirror is availed of.

The “chicken breast” of mouth breathing in childhood is different from the “violin” shaped chest of the rickety child. In the latter there are a *prominence* of the *whole sternum* and a vertical flattening of the sides of the thorax, leaving a large curve behind the costo-chondral articulation and a similar one in front, in addition to the horizontal depression of the lower thorax which is common to both kinds of deformity.

Prognosis.—This depends upon the early discovery of the condition, before the secondary effects have established themselves. If the trouble is purely a tonsillar one, it is comparatively easily removed by shaving off the organ. If the overgrowth is pharyngeal, little can be done until children are old enough to submit to the proper treatment. This may be done by the aid of ether as early as the second year. Hypertrophied tonsils begin to atrophy of themselves after puberty, and they have generally disappeared by thirty. The face and chest deformity may be outgrown if the cause be removed.

Treatment.—Most important are local measures to reduce the size of the overgrowth or to remove it and to prevent recurrence of acute attacks. The patient should be discouraged from hawking and clearing his throat. If the tonsils manifestly encroach on the faucial lumen, they should be shaved off by the guillotine or a bistoury or galvano-cautery loop. The same treatment is demanded by the pharyngeal adenoid growths. They may be curetted and sometimes scraped off by the finger-nail. There is sometimes copious hemorrhage, but it is usually easily controlled. If not requiring this, they should receive on alternate days or every third day applications of powdered alum; solution of iodine of the strength of iodine 8 grains (0.5 gm.); iodide of potassium 24 grains (1.5 gm.), glycerin half ounce (30 c. c.); of tincture of the chlorid of iron and glycerin equal parts; glycerole of tannin; or silver nitrate 1 to 20. The solid stick of the latter may be used if there be evident lacunar disease, but far better is electrolysis, by which the crypt is obliterated and the gland may be gradually destroyed. Spraying the nose with antiseptic solutions twice daily is helpful in maintaining cleanliness and purity of breath. Dobell's solution may be thus used; also dilute listerin or the *spiritus thymol comp.* given on page 310. Tablets containing various proportions of the ingredients therein named are made for solution in the little cup of the spraying apparatus. Great patience and perseverance are required, for the result is but slowly attained.

The general health of the patient should be carefully looked after. Suitable woolen underclothing should be worn, and it should be graduated to temperature and exposure. Cod-liver oil, iron, quinin, and strychnin are the best roborants. It is most important that every effort should be made in the direction of so hardening the patient that he may be able to resist the effects of exposure, a task not easy to accomplish. Cold bathing of the neck and throat, indeed, of the whole body is useful, while nourishing food, physi-

cal exercise, and outdoor life, with suitable clothing, are means to this end.

SIMPLE CIRCULATORY DERANGEMENTS OF THE PHARYNX.

Hyperemia of the pharynx is a very common condition in smokers. It is also almost always present when there is chronic nasal catarrh. Under these circumstances the mucous membrane is constantly red, angry looking, often streaked with mucus, and is very easily thrown into a state of active inflammation.

In such obstructions to the circulation as are caused by mitral valvular disease, cirrhosis of the liver, or pressure upon the ascending vena cava by aneurysm or tumor, there is venous stasis and the venules may often be seen distended. Occasionally they burst, producing small hemorrhages which stain the mucous secretion. The same causes may produce edema of the mucous membrane of the pharynx, and especially does this occur in Bright's disease. The edema may extend thence to the uvula, which becomes greatly swollen. In aortic regurgitation the capillary pulse may be seen in the pharynx, and the internal carotid also seen to throb strongly.

ACUTE CATARRHAL PHARYNGITIS.

SYNONYMS.—*Sore Throat; Simple Angina.*

Definition.—An acute inflammation of the mucous membrane covering the pharynx and tonsils, sometimes extending upon the palate.

Etiology.—Acute pharyngitis occurs at all ages, but is more frequent in children. Exposure to cold and wet is its most frequent exciting cause. The delicate are more predisposed than the robust, and where there is the hyperemia above referred to, a trifling cause lights up an inflammation. Rheumatism and gout are also frequent causes. Pharyngitis and tonsillitis are often associated.

Symptoms.—The first symptom is usually *pain* on swallowing, which is associated at first with a *dryness* and *soreness*, producing a desire to “clear the throat.” To this is soon added a *full feeling*, and then pain independent of swallowing. The inflammation may extend into the Eustachian tube, producing partial *deafness*, or into the larynx, producing *hoarseness*. There is a varying degree of constitutional disturbance, and sometimes the *fever* is quite high.

On examining the throat it will be found red and congested, sometimes plainly swollen, especially over the tonsils. There is often considerable mucous secretion. The various forms of ulcer of the tonsils described under tonsillitis may be associated with the pharyngitis, increasing the constitutional disturbance and local discomfort.

Treatment.—Many simple sore throats pass away without treatment. Astringent washes and gargles are indicated, but the patient should be warmly housed and even in mild cases had better go to bed. Twenty-four hours in bed is by far the best medicine for an ordinary cold. A gargle of alum or tincture of the chlorid of iron in the proportion of a teaspoonful of either to a full tumbler of water may be used, while applications of a mixture

of equal parts of the iron tincture and glycerin may be applied to the throat two or three times a day. Solution of nitrate of silver, 20 grains (1.3 gm.) to the ounce (30 c. c.), may be similarly applied, also the glycerole of tannin.

In severe cases cold cloths wrung out in ice water and applied to the outside of the throat, the clothing being protected by the interposition of a dry towel, make an excellent measure; or the little ice bags referred to in the treatment of acute tonsillitis may be applied to the throat, with a dry towel outside of them. Occasionally counterirritation by mustard is more efficient, as every throat does not bear cold equally well.

The fever should be met in the usual way by aconite, sweet spirit of niter, and citrate of potash, while chlorate of potash and chlorid of iron should also be administered internally. The bichlorid of mercury may be added under the same circumstances as in diphtheroid tonsillitis. There is no advantage in giving large doses of iron. They are not absorbed and the excess remaining in the alimentary canal locks up the secretions and causes irritation. From two to ten minims (0.12 to 0.6 gm.) every two hours are quite sufficient. The bowels should be kept open, and the treatment may be advantageously commenced with a saline aperient, such as calcined magnesia, the solution of the citrate of magnesium, or Hunyadi water.

Where the disease is traceable to rheumatism or gout, suitable treatment for these diseases should be instituted. The salicylates are the best remedies for both, but guaiacum has some reputation, the tincture or ammoniated tincture being the best preparation, given in doses of 5 to 60 drops (0.35 to 4 gm.).

CHRONIC CATARRHAL PHARYNGITIS.

SYNONYMS.—*Clergyman's Sore Throat; Granular Pharyngitis; Chronic Angina; Chronic Follicular Pharyngitis.*

Definition.—Chronic pharyngitis, when not associated with ulceration, presents much the same appearance as chronic hyperemia, plus the addition of a granular appearance due to enlargement of lymphatic glandules, with which the pharynx is studded.

Etiology.—The disease is rather one of adults than children. Its causes are repeated attacks of acute pharyngitis and excessive smoking and alcohol drinking. Chronic nasal catarrh with its irritating discharges trickling down the fauces is a frequent cause, as is also nasal obstruction and disease of the third or Luschka's tonsil. It also occurs in those who use their voices largely, as hucksters, public speakers, and singers, while the inhalation of dust and irritating gases is also held responsible.

Treatment.—This is very much more unsatisfactory than in the acute type. It is most important to treat the causes or remove them. Post-nasal catarrh is responsible for so many cases that the post-nasal region should at once be investigated and its diseases treated. Smoking and the use of alcohol, if responsible, should at once be discontinued. The same local measures useful in the acute disease may be employed in the chronic, but they are less promising as to results. The little granules, which are apparently a source of irritation as well as a result, can be removed only by the galvano-cautery needle. Other measures to this end are unsatisfactory

and insufficient. The general health of the patient should be carefully looked after, and occupations tending to keep up the irritation should be discontinued.

ULCERATION OF THE PHARYNX.

The ordinary form of chronic pharyngitis rarely produces ulceration. Syphilis, tuberculosis, diphtheria, inflammation, and lowered nutrition, such as is found after the infectious diseases, like typhoid fever and scarlet fever, are frequent causes of sluggish ulcers indisposed to heal. The chief symptom of these various varieties of ulceration is pain, increased during deglutition, with more or less copious mucous secretion, which often adheres firmly to the pharynx.

Diagnosis.—It is not always easy to distinguish the different forms of ulceration. The *syphilitic ulcer* is least painful, in fact often painless, and is commonly situated in the posterior wall of the pharynx. It occurs both as a secondary and tertiary symptom. As a secondary symptom it is superficial and associated with mucous patches, while as a tertiary it forms the cavity left by a softened, gummy tumor, and is correspondingly deep. It is associated with the history of syphilis.

The *tubercular ulcer* is more painful—indeed, the most painful of all. It is irregular, not very deep, has a grayish base, and is also seated in the posterior wall of the pharynx, considerable areas of which may be involved, producing an uneven, worm-eaten appearance. It is associated with tuberculosis elsewhere. The *indolent ulcers* of lowered nutrition are also often insidious and occasion few active symptoms. After the separation of the membrane in diphtheritic pharyngitis there are sometimes left ulcers more or less extensive, which are slow to heal.

Treatment.—This consists locally in the application of stimuli and antiseptics, the former represented by nitrate of silver and the latter by thymol and its class, together with general treatment appropriate to the condition, such as tonics of which iron and quinin are the types.

PHLEGMONOUS PHARYNGITIS.

Definition.—This term is applied to any suppurating inflammation involving the pharynx, however induced, except post-pharyngeal abscess, which is a separate condition. It may be a part of the process which constitutes suppurating tonsillitis or quinsy, extending to the adjacent pharyngeal structures. It may include the acute infectious phlegmon of the pharynx described by Senator, in which, along with swelling of the external neck, the pharyngeal mucous membrane is swollen and injected, and becomes rapidly the seat of suppuration. It may include similar conditions induced by injury, the inhalation of scalding liquids, or the swallowing of corrosive poisons. Or it may be the result of pharyngeal erysipelas or of the lodgment of foreign bodies.

Symptoms.—These are correspondingly intense. There is *painful swelling*, interfering not only with deglutition, but also with respiration. There is high *fever* and rapid *exhaustion*. It may terminate in *gangrene* of the part or gangrenous pharyngitis.

Treatment.—The treatment is locally antiphlogistic, including cold by ice or otherwise, scarification and liberation of pus at the earliest possible moment, together with restorative and stimulating internal measures. If gangrene results, cauterization and antiseptic applications must be added. The aid of the surgeon should be early sought.

POST-PHARYNGEAL ABSCESS.

Definition.—A phlegmonous inflammation behind the proper pharyngeal tissue, subperiosteal in some instances, arising in suppurative inflammation of the post-pharyngeal lymphatic glands or caries of the cervical vertebræ. It is a disease of children and adults, more frequently of the former, often a sequel of one of the pharyngeal conditions already considered, favored by bad hygiene and depraved constitutional states, hereditary or acquired.

Symptoms.—Its symptoms are intense *pain*, *swelling*, and interference with deglutition and respiration, with more or less early appearance of a *tumor* in the posterior wall of the pharynx, which can generally be recognized by the finger before it can be seen—a fact which emphasizes the importance of frequent examination of the throat by the finger in diseases of these parts. There is also *stiffness of the neck*, sometimes *nasal voice* or even hoarseness, suggesting croup and edema of the glottis, but there is never absolute loss of the voice, as in the latter, while croup and edema are not associated with painful deglutition.

Treatment.—This consists of incision of the abscess as soon as discovered. It should be made in the median line and the head should be brought forward to avoid the entrance of pus into the larynx. Anodynes are necessary to overcome the intense pain, but it is to be remembered that they may so mask the symptoms as to permit destructive inroads of the disease before it is discovered.

DISEASES OF THE ESOPHAGUS.

EXPLORATION OF THE ESOPHAGUS.

This is a manipulation so frequently necessary that its description is demanded at the outset.

The esophageal bougie is made of flexible whalebone, on the end of which is firmly fixed an olive-shaped piece of ivory. The ivory ends are made of different sizes. The ordinary stomach tube may also be used for the same purpose, and is the safest instrument to use in earlier exploration.

In introducing the bougie, or tube, the patient should sit on a low chair with his head thrown back. The index-finger of the left hand is then introduced well back into the pharynx, along the median line. The bougie, or tube, is then passed along the side of the finger to the posterior wall of the pharynx and then down into the gullet. Usually a slight resistance is encountered at the level of the cricoid cartilage, but it is easily overcome.

and after this the descent is easy. Caution should, however, always be exercised, as the bougie has a few times been pushed through an ulcer of the esophagus into the pleural cavity or lung, while I have also known ulceration to be produced by its repeated use in simple nervous spasmodic obstruction.

ESOPHAGITIS.

ACUTE ESOPHAGITIS.—An acute inflammation of the esophagus is practically limited to inflammation induced by the swallowing of very hot or corrosive liquids, such as strong acids and alkalis, or by the lodgment of foreign bodies. It is true, diphtheritic inflammation sometimes extends from the pharynx downward, while the esophagus has also been invaded by a vesicle of smallpox, but these conditions are not likely to be differentiated from the primary disease. Mycotic esophagitis, producing stenosis of the esophagus in sucklings, has been alluded to as a possibility on page 308.

Morbid Anatomy.—Appearances vary with the cause. In addition to the usual redness, sloughing and disintegration of tissue may result. Milder degrees of inflammation produce less conspicuous alteration. A granular appearance may succeed desquamation of the epithelium. Diphtheritic false membrane presents the same characters here as elsewhere.

Symptoms.—These are chiefly *pain* beneath the sternum, increased by swallowing, which in extreme degrees of inflammation becomes agonizing and, indeed, renders swallowing impossible. Copious mucous secretion is sometimes present, which may be raised or regurgitated to the fauces and expectorated or passed into the stomach. Milder grades of inflammation are without symptoms, intermediate grades present corresponding symptoms. If healing results after destructive inflammation, the cicatricial tissue behaves as it does everywhere else, contracting and distorting the parts, oftentimes with resulting stenosis.

Treatment.—Little can be done to aid healing. For the most part, therefore, it must be given over to nature. If deglutition is possible, demulcents may be used, while the swallowing of pieces of ice sometimes gives comfort. When deglutition is impossible, the patient must be fed with nutritious enemata. The treatment of resulting stenosis is that of stricture of the esophagus, which see.

CHRONIC CATARRHAL ESOPHAGITIS.—This affection is sometimes favored by valvular heart diseases, cirrhosis of the liver, or other cause of venous obstruction. The resulting affection is a catarrhal inflammation associated with mucus-secretion. A hemorrhoidal state of the veins may be thus caused, which may proceed to rupture, with fatal termination.

SPASM OF THE ESOPHAGUS.

SYNONYM.—*Esophagismus*.

This is not an unusual affection in hysterical women, and even in male hypochondriacs. These are generally past middle life. It also occurs in hydrophobia, chorea, and epilepsy. The spasm is commonly excited by an

effort to swallow solid food, and rarely even liquids act similarly. A possible result of spasm is a dilatation, as shown in a case of my own, to be again referred to.

Diagnosis.—The diagnosis is readily made by the bougie, which, though it may be stayed for a minute at the seat of spasm, ultimately passes it without the application of force. It is also associated with other symptoms of hypochondriasis, while extreme pain, the gradual emaciation, weakness, and ultimate cachexia of cancer are absent. Errors of diagnosis have, however, been made, and death has even occurred when autopsy disclosed no lesion to explain it.

Treatment.—This is that of the hypochondriacal state and the frequent use of the bougie, of which the moral effect is also good. One introduction has sometimes been sufficient. On the other hand, I have known the repeated passage of a bougie to have produced ulceration, whence the caution already enjoined in the use of the instrument.

CANCER OF THE ESOPHAGUS.

This is usually a hard epithelial tumor, most frequent in the middle third of the esophagus, though it may involve the cardiac orifice of the stomach, and more rarely other portions. E. Rindfleisch, especially, describes a softer and more superficial form, which invades larger areas in a diffuse way. It is rather more frequent in men, and appears first as zonular infiltration of the mucous membrane, which ulcerates. The resulting ulcer may also extend around the tube, acquiring a width of two or three inches (5 to 6 cm.). The primary and usually permanent result, unless ulceration does away with it, is a stenosis of the esophagus, followed by dilatation of the tube, with hypertrophy of the walls above the stenosis.

Symptoms.—*Difficult and painful deglutition* is usually the first symptom of stenosis, though *pain*, independent of deglutition, may precede. *Swallowing* becomes more and more difficult, and ultimately, even liquids may be regurgitated. *Regurgitation* of food may not be immediate, and the date of its appearance is usually dependent on the seat of the obstruction and extent of dilatation above it. A discharge of *blood* and mucus may attend an effort to introduce the bougie. Death commonly takes place from exhaustion or actual starvation. But before this happens there may be a rupture into the larynx or a bronchus, producing death by suffocation, by gangrene, or by an inhalation pneumonia. There may be ulceration into the aorta or one of its large branches, causing fatal hemorrhage; into the pericardium, producing fatal pericarditis. Ulceration into the mediastinum or erosion of the cervical vertebræ sometimes occurs, with more delayed fatal ending. Emphysema is a sign of rupture into the lung. The adjacent lymphatic glands of the neck are sometimes invaded. Rarely the disease is latent throughout its entire course.

Diagnosis.—This may have to be delayed a short time, but is soon clear. The continued obstruction, the emaciation, and the weakness soon distinguish the case from one of spasmodic stenosis. Compression by adjacent growths should be remembered as a source of obstruction, aneurysm being perhaps the most frequent cause of this kind; but aneurysm may generally be recognized by its other signs.

Prognosis.—This is always ultimately fatal.

Treatment.—Treatment can only be made to prolong life. The bougie should not be used after the diagnosis of cancer is established, because of the danger of causing perforation. So long as liquid food can pass the obstruction it should be used; after this, nutritious enemata in the manner recommended under cancer of the stomach. Esophagostomy or gastrostomy may be presented for the patient's consideration. The former promises nothing, but life may be prolonged by the latter.

STRICTURE OF THE ESOPHAGUS OTHER THAN CANCEROUS.

Etiology.—The most frequent cause after carcinoma is contraction of the scar tissue of a healed ulcer, caused, commonly, by some corrosive agent or syphilis. Next in frequency is pressure by external tumors, such as aneurysm, enlarged lymphatic glands, or mediastinal tumors. Next is congenital narrowing, and, finally, polypoid tumors projecting from the mucous membrane. If the stenosis be cicatricial, the precise cause is to be determined by the history of the case, and its situation by the esophageal bougie.

Symptoms.—These are those of obstruction, described under cancer and spasm, with or without the painful element; to which may be added those of dilatation of the esophagus, to be next considered.

Treatment.—This is altogether by the careful use of the bougie. Dilatation of the cicatricial stenosis is often quite successful. The largest bougie should be first introduced very gently, without force, really as a sound, *as far as the obstruction only*. Then smaller sizes should be tried until one is found which will pass, and from this point, again, larger sizes should be successively employed. At each sitting the bougie originally passed with ease should be started with and followed more rapidly by the larger sizes, as the physician becomes familiar with his patient's case.

In congenital cases less is to be expected, while obstruction by external growths, unless they be removable, is practically irremediable, and grows gradually worse. Even cicatricial stenosis may be such that the smallest bougie cannot pass, in which event nourishment by the rectum alone remains, unless gastrostomy be decided on.

DILATATION OF THE ESOPHAGUS.

Dilatation of the esophagus may involve the whole circumference of tube, when it is known as *diffuse* or *total*; or it may affect only one spot, when it is circumscribed, or constitutes a *diverticulum*.

Diffuse Dilatation.—In every case of stenosis of the esophagus, from whatever cause, there is sooner or later dilatation above it, delayed at first by hypertrophy of the muscular coat, which is thus enabled to force the food through the narrowing. Sooner or later this coat becomes paralyzed, the wall yields to the pressure of accumulated food, and dilatation follows. The resulting sac is usually spindle-shaped, but may be cylindrical, and is naturally larger the lower the seat of obstruction.

Rarely dilatation occurs without previous organic stenosis. It would

appear, however, that it must be preceded either by some traumatic cause which weakens the wall of the tube, or by repeated spasmodic stenoses. The fact remains that such dilatations occur.

Diverticula.—Diverticula or circumscribed pouches in the walls of the esophagus are of two varieties. They have been especially studied by Zenker, who has divided them into *pressure* diverticula and *traction* diverticula according to their mode of origin.

Traction diverticula are the more frequent, yet clinically are of less interest because often not recognized until their subjects are on the necropsy table. They are small, scarcely ever exceeding a centimeter (0.4 in.) in diameter, and relatively frequent in children. They are ascribed to some traction effect exerted on the wall of the esophagus. This may be, as Rokitsansky and Zenker suggested, due to the contraction of a tissue which has formed adhesions to the esophagus. Such a tissue is afforded by the bronchial glands, which become inflamed, caseate, and contract, and as they are situated at the bifurcation of the trachea, the more frequent occurrence of traction diverticula at this situation in the anterior wall of the gullet is thus explained. Such diverticula may be multiple.

Pressure diverticula are much rarer. They occur almost always in men, rarely in children. They are found most frequently at the junction of the pharynx and esophagus, where the muscular wall, formed chiefly by the inferior constrictor of the pharynx, is weakest, and are caused by pressure from within. This may be exerted by the bolus of food itself, especially if it be habitually large, as in rapid eaters, while its operation may be further facilitated by some traumatic injury to this part of the throat, such as may be caused by the lodgment of a bone.

The sac is found to be bounded by mucous membrane and thickened submucous coat, the muscular coat giving way to let the mucous coat pass through it, as in a hernia. It is found invariably in the posterior wall, and hangs in front of the spinal column.

Symptoms.—In cases of *diffuse* dilatation originating in stenosis, apart from the inference that where there is stenosis there must ultimately be dilatation, the first symptom to attract attention is the *feeling* on the part of the patient that his *food does not enter the stomach*, but lodges higher up, though the quantity swallowed is evidently more than would be held by an esophagus of ordinary caliber; usually, sooner or later, follows the *regurgitation*, or gulping up of this accumulation. The same symptoms are said to attend dilatation without stenosis. The latter event can only be explained on the supposition that, in consequence of the paralyzed state of the muscular wall of the esophagus, there is no force to push the food down, while the gradual widening of the tube affords support for its lodgment, which is further favored if the enlargement takes the shape of sacculations or a pocket.

Traction diverticulum rarely causes symptoms. Those arising from pressure diverticulum are first those of *dysphagia*, as the diverticulum grows larger, and the food lodges more and more; *regurgitation*, though the sac is rarely thoroughly emptied, and the retained food sometimes undergoes decomposition, giving rise to fetid breath. The difficulties increase until after a while it is almost impossible to get food into the stomach, though extraordinary efforts are made by the patient to do so, with greater or less success. Complete closure results when the diverticulum becomes so large as to flex upon the gullet and compress it.

The sound should be used in the study of all forms of the disease. By its means the situation of the stenosis can be ascertained. Should it pass readily into the stomach, there is no stenosis, but there may still be a diverticulum, for at one sitting the sound may pass the opening into the sac, while at another it may enter it and resist further attempts to complete the transit. Zenker and v. Leube have devised a diverticulum-sound bent at an angle, so as to facilitate its entrance into the diverticulum, advantage being taken of the fact that we know about where these diverticula are most frequently found—that is, opposite the cricoid cartilage.

With the prolongation of the condition the proper nourishment of the patient becomes more and more difficult; he emaciates, grows weaker, and ultimately perishes from exhaustion unless carried off by some other disease.

The following case, recently under my care, illustrates the symptoms of the condition: C. G. was an actor, thirty-three years old when he came under observation. When only twelve years of age, while eating his supper, his food suddenly regurgitated and he had to leave the table. Returning, another effort was followed by the same result. The next morning his breakfast came up in the same manner. After a time he discovered that by rapidly drinking a large amount of liquid after each meal he could, by a great effort, cause most of the food to enter the stomach. This had to be done at every meal by some indescribable effort, which was painful and exhausting. Furthermore, it was rarely completely successful, some food being always regurgitated, commonly later in the day. Since twelve years of age this regurgitation has continued, and he loses, on the whole, about one-third of the food ingested, while at times his efforts to get it down are totally unsuccessful, in which event the full amount is regurgitated. Further, the difficulty of successfully getting food into the stomach is gradually increasing.

In this case there would appear to be a certain degree of stenosis, for while a part of the food can be forced to enter the stomach, and small sounds can be passed into that organ, larger ones cannot be made to enter. Yet from the suddenness of its occurrence and the early age of the patient, the stenosis, if one is present, has not arisen from the usual causes. Can there be a diverticulum? If so, it is lower than pressure diverticula generally are, and larger than other traction diverticula.

Treatment.—The treatment of diffuse dilatation and diverticula is essentially the same. It consists, first, in measures to maintain the nutrition of the patient. Generally he is able to ingest a certain amount of food by his own efforts, of which those detailed in the case of my own patient are an illustration. After this the stomach tube becomes the most ready way. This, too, he should be taught to use himself. Rectal alimentation may help somewhat, but is alone inadequate for any length of time, while the inconvenience of any and all of these procedures renders the patient anxious for more complete relief.

This may be accomplished by operation, by which diverticula have been successfully removed. The difficulties in the way of operation are, however, great. The operative treatment of dilatations due to stenoses resolves itself into that of the stenoses themselves. In both forms gastrostomy may be the ultimate measure that promises relief for a time.

DISEASES OF THE STOMACH AND INTESTINES.

DIAGNOSTIC TECHNIQUE.

The very great value that modern medicine has discovered in a proper technique for the diagnosis of diseases of the stomach makes its preliminary consideration indispensable to their sufficient and exact study. It is conveniently divided into the external and internal examinations.

EXTERNAL EXAMINATION.

This embraces inspection, palpation, percussion, and succussion or splashing. Because of the difficulty of separating the external examination of the stomach from that of the intestines they are usually considered jointly.

The most important point to be remembered in the medical anatomy of the stomach is that a very small part of it lies to the right of the median line, not more than one-fourth, the remainder occupying the upper left quarter of the abdominal cavity. The *cardiac orifice* is fixed behind the sternal attachment of the sixth or seventh cartilage on the *left* side, while the *pylorus*, more movable, lies on the *right* side, between the tip of the sternum and the conjoined seventh and eighth cartilages, and under the left lobe of the liver. The seats of both orifices—the cardiac and pyloric—and the outline of the stomach vary somewhat with the degree of distention, but when the stomach is moderately distended the highest part of the fundus is in the fifth interspace, at the mammillary line, and the lowest part of the organ in the median line, three to five cm. (1 to 2 inches) above the umbilicus in men and four to seven cm. (1.5 to 3 inches) in women.

The information given by *inspection* may be of no value whatever, or may possess considerable import. Commonly, the stomach and bowels are the seat of a moderate distention with gas—just enough to make precise information by this method unattainable. This is especially the case in little children and in men past fifty. In very thin subjects the stomach may be recognized in outline, and exaggerated contractions may even be seen in it and in the intestines. Such contraction does not, however, imply of necessity an effort to overcome obstruction at the pylorus or in the bowel below. It may be purely nervous. Morbid growths in the stomach may sometimes be recognized by inspection. So may many uneven growths of the liver in thin persons, while the end of a distended gall-bladder may, in rare instances, project at the edge of the thorax, near the end of the cartilage of the tenth rib on the right side. Epigastric pulsation is sometimes strikingly conspicuous. Enlargement of the superficial epigastric and abdominal veins is always to be looked for. More frequently there is a circumscribed distention recognized in the region of the stomach, or the entire abdomen may be distended, a symptom which may be due to atony, or, among others, points to some obstruction in the lower part of the bowels. In other instances the opposite state of undue flaccidity is observed—the belly flattening out laterally as the patient lies on his back, or falling forward when he stands up. The latter condition occurs especially in persons who have been corpulent and have grown thin, and in women who have borne many children. The patient may also be examined in the knee-elbow position, which

will permit movable tumors to fall forward and facilitate their recognition by inspection as well as by palpation.

Palpation furnishes at times more definite information than inspection. It should be practiced by laying the hand flat upon the abdomen and depressing the ends of the fingers as the hand is moved about, rather than by "poking" with the fingers of the extended hand obliquely placed. The abdominal walls, too, should be relaxed by semi-flexing the thighs on the abdomen and the legs upon the thighs. Thus we learn of the consistency and situation of various organs and abnormal growths, whether they are smooth or uneven, whether there is tenderness or tenseness, softness or hardness. In so doing, the degree of pressure must vary. Some pains are relieved by pressure, others aggravated. The former are more apt to be due to neuralgia or colic, the latter to be inflammatory. Our knowledge of the precise situations of morbid growths is often aided by changing the position of the patient. A tumor of the pyloric orifice of the stomach, which is more apt to be felt toward the median line, above the umbilicus, is also characterized by its greater mobility; as well as change of location with varying degrees of distention of the stomach. Such a tumor may be subject to a peculiar rotary motion.

Percussion of the gastro-intestinal region is practiced with the patient on his back in a relaxed position, like that described for palpation. A pleximeter is here conveniently used, and auscultatory percussion may be practiced with advantage. The phonendoscope may also be used to determine the outlines of these organs during scraping or rubbing. The stomach and intestines approach the surface in health in such a way as to make their limitation quite possible by percussion. They require, also, delicacy in discriminating shades of sound, more particularly as to pitch. The quality met with in percussing these organs is, for the most part, tympanitic, and it is chiefly variations in the pitch which are to be discriminated. The same organ may exhibit different degrees of pitch under different conditions. Thus, the stomach, when moderately distended with gas, gives a low-pitched tympanitic sound when percussed; when more fully distended, it gives a higher pitch; when distended to a maximum, it may give a dull sound, because all vibration is stopped. Given the stomach and intestine in an equal degree of tension, the stomach will respond to percussion with a lower-pitched tympany than the intestine because it is a larger cavity. This is sometimes spoken of as less tympanitic. Sometimes the stomach percussion note is ringing, amphoric, echoing. By means of these differences, when present, we may distinguish one hollow organ from another. Again, the presence of liquids or solids in the stomach influences the percussion note.

The hollow viscera *en masse* can be mapped out by determining the boundaries of the solid viscera around them. But we want to do more than this: we want to separate one hollow organ from another—the stomach from the small intestine, the small intestine from the large. For this the patient must be recumbent. As stated, the stomach tympany is ordinarily lower pitched than the bowel tympany. Bearing this in mind, we can generally determine the stomach boundaries when the organ is moderately distended with gas. The upper limit of stomach tympany, recognizable by percussion, corresponds with the lower edge of the left lobe of the liver. To the left of the apex of the heart, the stomach tympany is mixed with the resonance of the lung. At this point, about the fifth rib, is the cardiac end

of the stomach. Percussing downward and a little backward from this point, we are generally able to find a difference of note—a higher pitch, a purer tympany, belonging to the transverse colon. Keeping close to this line and following it anteriorly, we find it crosses the left edge of the thorax at about the cartilaginous attachment of the tenth rib, the median line just above the umbilicus, and passes thence upward to the junction of the right lobe of the liver with the edge of the thorax. It is the line of the greater curvature of the stomach.

Traube's *half-moon space* is a term applied to the area bounded above by the lower border of the left lung, approximately determined by the upper edge of the sixth rib as far as the axillary line; on the right by liver dullness, on the left by splenic dullness; and below by the costal arch, yielding a tympanitic note when the stomach is empty and distended, but a flat note to percussion when the stomach is full or there is pleural effusion on the left side. Leichtenstern has applied the name *pulmono-hepatic angle* to the point of junction between the lower edge of the left lobe of the liver and the lower border of the left lung. The tip of this angle is behind the sixth rib, just below the apex seat, and is bisected by the pleural space, which is filled by the lung only during deep inspiration. The stomach fills in this angle, and it is an area pretty constantly maintained. The outline of the stomach may be made more distinct by having the patient drink a glass of water just before the examination; or, as originally suggested by Frerichs, by taking in rapid succession the two portions of a Seidlitz powder—tartaric acid and sodium bicarbonate—or a glass of soda-water.

A better method of outlining the stomach is to inflate it with air, as suggested by Runeberg, by means of the double bulb of a spray apparatus. This should be done, if possible, in connection with the use of the tube for some other purpose, as removing the stomach contents after a test meal. The possibility of air passing through the pylorus is to be remembered, but, commonly, if any excess is introduced it passes out alongside of the tube. This is not the case with carbonic acid gas, which excites rather a spasmodic contraction of the cardiac orifice. Both gas and water may distend the stomach beyond the limits described, but the normal limit of the lower curvature may be put above the umbilicus, although it cannot be said to be abnormally low when at the umbilicus, an event not unusual after fifty years of age. As already mentioned, the greater curvature is not quite so low in women as in men, and in working women not so low as in those of leisure. When the lower curvature is below the umbilicus, the stomach may be said to be dilated. It is always desirable, if possible, to examine the stomach with the patient standing as well as lying.

As stated, the percussion note of the large intestine is higher pitched and more purely tympanitic than that usual to the stomach. When containing feces it is rendered duller, and in consequence of this fact there is often less resonance in the left iliac fossa than in the right, although feces may also accumulate in the latter, and an impaction in the head of the colon may give positive dullness. The colon may also be artificially distended *per rectum* with air, if desired, for examination.

The percussion note of the small intestine is usually still higher pitched than that of the large, and by this it may be distinguished from that bowel, if not filled with solid matter or liquid. The differences in percussion note referred to are not always equally well marked, and it is not always possible in consequence, to demark the organs. Especially difficult is it at times thus

to distinguish the transverse colon, when distended with gas, from the stomach above it. If the stomach be filled with water, a dull note is brought out on percussion, which contrasts strongly with the tympanitic note of the gas-distended colon.

Whether determined by inspection, palpation, or percussion, a stomach the greater curvature of which reaches the umbilicus or below is abnormally dilated, while certain dilated stomachs go far below the umbilicus. The vertical diameter of the normal stomach, from the highest to the lowest points of tympany, as determined by Wagner, was 11 to 14 cm. (4.4 to 5.6 inches) in men, and about 10 cm. (4 inches) in women. The width of the zone was 21 cm. (8.4 inches) and 18 cm. (7.2 inches). Other measurements are somewhat different, so that some latitude must be allowed.

Auscultation has a less useful application to diagnosis of diseases of the stomach. It is confined to the so-called *deglutition murmurs*, of which there are two. They are best heard with the stethoscope to the left of the spinal column, behind, in the neighborhood of the ninth or tenth rib; in front, to the left of the xiphoid. One is heard at the beginning of swallowing, when the food is transmitted from the pharynx into the esophagus, and is termed by Ewald the *primary* deglutition sound. It is heard all along the esophagus, and has no significance. It is a hissing sound, as if produced by fluid squirted directly into the stethoscope (*Spritzgeräusch*). Six or seven seconds later, corresponding with the contraction of the lower segment of the esophagus, may be heard the *second* deglutition sound, consisting of a series of tones rapidly following one another, either gurgling, clucking, sprinkling, or splashing (*Pressgeräusch*). It is said to denote a relaxation of the cardia and the direct passage of food into the stomach. It is quite constant, and is usually absent when there is obstruction of the cardiac orifice.

It is the absence of the deglutition murmurs rather than their presence on which diagnostic value depends; that is, they are apt to be wanting in obstructive disease of the cardiac orifice, although too much stress must not be laid upon such absence, since they are not always present in health, and repeated observation is required before conclusions dare be drawn.

Gastroscopy and *Gastrodiaphany* have not as yet been sufficiently perfected to be available in diagnosis of stomach affections.

The investigation of the large intestine by percussion is sometimes aided by distending the bowel with gas or air *per rectum* in one of the various ways suggested for the stomach, the bowel being previously evacuated by an enema. The large bowel may also be explored for a considerable distance from its anal end by specula.

INTERNAL EXAMINATION OR CHEMICAL EXAMINATION OF CONTENTS.

For removing the gastric contents for examination the stomach tube or catheter is used. That usually employed is a thoroughly soft, flexible, red rubber tube, open at the inner end, or, if closed at the end, provided with lateral openings, like a Nélaton's soft catheter. (The latter is advised because it has happened with the open-end tube that a portion of sound gastric mucous membrane has been aspirated into it.) The tube should be about 95 cm. (about 3 feet) long. From the fundus of the stomach to the incisor teeth is 60 to 65 cm. (about 2 feet), and the tube is usually marked at this point, thus enabling one to judge whether it has entered the fundus. Suf-

ficient lubrication is secured by moistening it with water. It is carried into the back part of the pharynx in the manner described for the sound (p. 323), when the patient is directed to swallow. At the end of the act of deglutition the tube is pushed gently downward, and the patient again directed to swallow. This is kept up until the tube enters the stomach. A long tube permits the stomach to be emptied by siphonage *after a little pressure on the abdomen* has been exerted by the hand to start the motion of the contents. This is safer than aspiration by a pump, as sometimes practiced.

For analysis of the gastric contents the *test meal* commonly employed is the *test breakfast* of Ewald and Boas, consisting of an ordinary roll * weighing about 35 gm. (9 drams) and 300 c. c. (10 fl. oz.) of water or weak tea without milk and sugar. At the end of one hour after the meal is ingested the stomach is emptied by expression and siphonage, as described. There should be 20 to 40 c. c. It has happened to me to fail to secure anything after such a test meal from the rapid disappearance of the products of digestion. In such event two rolls may be taken at the next meal and the liquid increased to 400 c. c. (13 fl. oz.). It is first examined by the microscope for blood or other abnormal morphological constituents, and then filtered, being previously well shaken.

The Leube-Riegel *test dinner* may be used. It consists of beef-soup, 400 gm. (13.3 oz.); beefsteak, 200 gm. (6.6 oz.); bread, 50 gm. (1.6 oz.), and water 200 c. c. (6.6 fl. oz.). This should be removed for testing at the end of four hours.

Acids of Digestion.—In healthful conditions, in ten or fifteen minutes after food ingestion the gastric contents are acid, the acidity depending on free acids or acid salts, the latter including chiefly acid phosphates of sodium and potassium introduced in various amounts with food. At this stage the free acid recognized is lactic, which is either introduced with food or is formed in the lactic acid fermentation out of carbohydrates, especially sugar. Up to thirty to forty-five minutes the lactic acid predominates, while the tests for hydrochloric acid may be negative. Then comes a stage in which traces of HCl can be demonstrated, coexisting with, it may be, lactic acid. Finally, the lactic acid disappears altogether, and at the end of an hour HCl only should be present. HCl is present from the beginning, but its recognition is interfered with, partly because the first secreted immediately combines with bases until these are neutralized. Free HCl gradually increases in amount until at the acme of digestion it reaches 0.15 to 0.2 per cent. after a light meal, and 0.2 to 0.33 per cent. after an abundant meal.

The *reaction* of the removed contents may be determined by blue litmus, but *Congo-red* paper or *tropæolin* paper † may be used, the former being turned blue and the latter brown. These reactions point also to *free acids* in general, being uninfluenced by acids when combined with bases. Nor can Congo-red or tropæolin be relied upon to differentiate between mineral acids and organic acids.

* Such a roll, containing about 7 per cent. of nitrogen, 5 per cent. fat and 4 per cent. sugar, 52.5 per cent. of non-nitrogenous extractive substances, and 1 per cent. of ash, includes, therefore, the usual elements of a mixed diet.

† These papers are made by dipping strips of filtering paper into watery or alcoholic solutions of the anilin dyes, Congo-red or tropæolin (l'orange Poirier), allowing to dry, and preserving for use. The paper is, however, less delicate than the solution.

The Congo-red strikes a beautifully *sky-blue* reaction with a solution containing but 0.02 per 1000 of HCl; a purplish, but not distinctly different, reaction with lactic acid. *Acid salts produce no change.* The tropæolin solution is dark yellowish-red, and a solution of free acid, 0.025 to 1000, changes it to a deep dark brown. It is slightly less delicate, therefore, than the Congo-red. *Acid salts, as acid sodium phosphate, make it straw-yellow.* In all of these tests it is necessary to use an excess of the fluid to be tested. This is accomplished by placing five or ten *drops* of the reagent in a test glass or porcelain capsule and adding one or two c. c. of the filtered contents.

To Test Qualitatively for Free Hydrochloric Acid Only.—For this Günzburg's phloroglucin vanillin or Boas's resorcin test is used. Günzburg's reagent consists of *phloroglucin* two grams (30 grains), *vanillin* one gram (15 grains), *alcohol* 30 c. c. (f 3̄j). The solution is pale yellow, and has a decided odor of vanilla. On exposure to light it assumes a dark golden-yellow. It must, therefore, either be kept in dark-hued bottles or freshly made as required. A drop or two of the reagent is placed on a porcelain plate or capsule with an equal quantity of the gastric filtrate, and a gentle heat applied, not to boil, but simply to evaporate. If free HCl is present, very soon a beautiful rose-red tinge appears at the edge of the mixture, or red stripes will be observed. Blowing at the edge will favor the appearance of the red stripes. This test is unmistakable, and surpasses all others in delicacy, being available when HCl is present in the proportion of 1 to 20,000 or 0.5 mille. The reaction is not simulated by albuminates nor interfered with by salts present in the normal proportion, nor by organic acids.

Boas's test for free HCl is based upon the fact that resorcin strikes a similar reaction with hydrochloric acid. The solution consists of:

Resublimed resorcin,	5 parts (gr. lxxv)
White sugar,	3 parts (gr. xlv)
Dilute alcohol,	100 parts (f 3̄ iiiss)

Three to five drops of the reagent are poured into a porcelain dish and an equal quantity of stomach contents added. Heat is applied as in Günzburg's test, and a *purple-red* color appears at the edge of the drop. It is said also to detect 0.05 per mille of HCl.

To Estimate the Total Acidity, Including Free and Combined Acids and Acid Salts.—The total acidity of gastric contents includes free acids, viz., hydrochloric, lactic, and sometimes other organic acids; combined acids, consisting of acid phosphates; and loosely combined acids, in the shape of HCl-albumins, HCl-albumoses, and peptones. The reaction of the filtered fluid being determined by litmus paper, the total acidity is then determined by titration. A Mohr's burette is filled with a decinormal solution of caustic soda. Ten c. c. of the filtered solution are placed in a beaker and one or two drops of an alcoholic solution of phenol-phthalein added as an indicator. The solution is then slowly dropped from the burette until the red color produced in the fluid by the action of the alkali on the phenol-phthalein no longer disappears on shaking. As a rule, the acidity of the gastric contents, an hour after such a meal, requires 4 to 6 c. c. of the decinormal solution to neutralize it in normal digestion. Figures above and below this are therefore abnormal. The acidity may be expressed in percentage according to the amount of decinormal solution used. Thus if 4 c. c. were required to neutralize 10 c. c., there would be 40 per cent., or if 6 c. c., 60 per cent. *total acidity*.

If the acid reaction is due to *free HCl alone*,—i. e., if there are no organic acids present to contribute to the total acidity,—this titration will represent the total quantity of HCl, and its percentage is easily estimated. One c. c. of the decinormal soda solution is equivalent to 0.00365 gm. HCl.* If, therefore, the number of cubic centimeters used to neutralize 10 c. c. of the solution be multiplied by 0.00365, and again by 10, the result will be the actual percentage of HCl. Thus, if 6 c. c. of the decinormal solution be used, the percentage will be $6 \times 0.00365 \times 10 = 0.219$, within the normal range,

* Decinormal solution of soda $\frac{N}{10}$ NaHO=4 gm. Na HO dissolved in 1000 c.c. distilled water. Each cubic centimeter of this solution exactly neutralizes 0.00365 gm. HCl.

which is from 0.15 to 0.24 per cent.; if 4 c. c. be used, the HCl percentage will be $3 \times 0.00365 \times 10 = 0.10$, or less than normal.

Total Free HCl.—The *quantitative* estimation of free *hydrochloric acid* may be made by Mintz's method, the Krieger-Cohnheim method, or by Töpfer's method. The former is as follows: To 10 c. c. of the filtered gastric contents add the decinormal soda solution from a burette until Günzburg's reagent no longer gives a reaction with a drop of the gastric fluid. Thus, if 2.8 of the decinormal solution are so used, the percentage of free hydrochloric acid will be $2.8 \times 0.00365 \times 10 = 0.1$ per cent.

The Krieger-Cohnheim method is regarded by David Edsall as far superior to Töpfer's method.* It is based upon the fact that phosphotungstic acid and the salts of this acid precipitate native albumins and the products of their digestion in combination with phosphotungstic acid. The method, as given by Edsall, is as follows: The calcium phosphotungstate is prepared by making a 4 per cent. solution of commercial phosphotungstic acid, heating, and adding calcium carbonate until, after gentle boiling, the reaction becomes neutral; then filter. The solution may be kept indefinitely. In carrying out the test determine the total acidity; then to 10 c. c. of gastric contents add 30 c. c. of the calcium phosphotungstate solution, filter off the precipitate, wash the filter, collecting the washings with the filtrate, and titrate the filtrate and washings. Subtract the second result from the first, and the figures obtained represent the acidity due to combined HCl. Rosolic acid is used as an indicator in each case. The free HCl is estimated by titration with phloroglucin-vanillin, and the total amount of HCl is obtained by adding the results for the free and the combined HCl.

If free HCl is absent decinormal solution is added until a marked reaction for free HCl appears, the amount added being known, and the method is then carried out. Any excess over the amount added that may be found is then due to combined HCl. Dr. Edsall suggests a modification of the process that hastens the result, viz., filtering into a graduated cylinder after the precipitation, taking 20 c. c. of the filtrate, titrating this, and doubling the result. This avoids loss of time in filtering and washing. The results in the first titration are better if the stomach contents are diluted about five times, as the color change with rosolic acid is then sharper.

For Töpfer's method the reader is referred to treatises on diseases of the stomach, and manuals on diagnostic technique.

To Determine the Loosely Combined HCl.—It may be that there is no evidence of the presence of free acids, inorganic or organic, and yet the gastric contents will redden litmus. Such acidity is due to loosely combined acids. These are decomposed by calcic and sodic carbonate, and are therefore included in the estimation of total acidity, but do not respond to the test for free acids. The acid thus combined is commonly HCl, forming HCl-albuminates, HCl-albumoses, and peptones. While organic acids may be similarly combined, they are insignificant in amount and may be ignored. These loosely combined acids are also destroyed by combustion.

When free HCl is present, the estimation of the loosely combined HCl is an easy matter. We have simply to estimate the total acidity and the HCl, preferably by Töpfer's method,—which removes also the organic acids and acid salts,—subtract the latter from the former, and the difference is the loosely combined HCl.

* See "A Critique on Certain Methods of Gastric Analysis," by David L. Edsall, "University of Pennsylvania Medical Bulletin," April, 1907.

In cases where there is no free HCl and the contents are still acid, quantitative methods are complicated and only approximate at best. We may, however, by a qualitative test for chlorin by the Ewald-Sjöqvist method, which tests only the chlorin in the organic combination, ascertain whether some of the combined acid is HCl, and thence whether the deranged acid secretion implies a diminution or a total loss of function of the secreting cells. Mix 10 c. c. of the contents with 0.5 gm. (half a salt-spoonful) of barium carbonate in a platinum capsule. This mixture is evaporated and the residue fused to a red heat only in order to avoid too high a temperature. The fused mixture is treated with 50 to 75 c. c. boiling water and filtered. To this filtrate, when cooled, 5 to 10 c. c. of a saturated solution of sodium carbonate are added, by which the entire $BaCl_2$ is converted into $BaCO_3$, and thrown down as a flocculent precipitate if chlorin is present. The presence of organic chlorin compounds thus shown indicates that some of the combined acid is HCl.

To Determine Acid Salts.—To 15 c. c. of gastric contents in a beaker add enough calcium carbonate to neutralize the free and organically combined acids. Stir the mixture thoroughly, expelling the carbonic acid gas generated by passing a current of air through it, using for this purpose a glass tube attached to the bulb of a Davidson's syringe. Avoid blowing air from the lungs, as this contains CO_2 . Filter, take 10 c. c. of the filtrate and titrate with the decinormal soda solution, adding phenolphthalein as an indicator. The number of cubic centimeters used indicates the acid salts, and this, divided by 2, gives the acid phosphates.

Determination of Organic Acids.—These include lactic acid, acetic acid, and the true fatty acids, especially butyric. Acetic acid and fatty acids are not formed during normal digestion, and, if present, as they sometimes are, they are either introduced with the food or are produced in a fermentation of the carbohydrates set up by bacteria introduced with the saliva.

The physiological presence of *lactic acid* during what may be termed the first stage of digestion, heretofore regarded as physiological, is now called in question, especially by Boas. Boas, because of his recent discovery that all baker's bread contains lactic acid, substitutes for the ordinary test meal a thin gruel made of a tablespoonful of oatmeal flour to a quart of water and seasoned with salt. With this meal he maintains that lactic acid is never found in the stomach *unless cancer is present*. The matter, however, is still *sub judice*, though the following careful data, gathered from the experiments of Ellenburger* and Ewald, on the subject indicate that there is a primary evolution of lactic acid:

Kinds of Food.	Number of Observations.	Number of Times Lactic Acid was Found.	Number of Times Lactic Acid was Absent after Taking Food.	Time (in Minutes) after Taking Food at which Lactic Acid was Found.	Free HCl, When First Appeared:
Mixed diet.	31	26	5	10-100	After 120 minutes.
Bread.	31	13	18	10-30	After 30 minutes.
White of egg.	15	1	14	75	Seldom before 60 minutes.
Scraped meat.	23	17	6	10-100	Seldom after 120 minutes.

* Boas, "Deutsche med. Wochenschrift," 1893, pp. 913-940; Ellenburger and Hoffmeister, "Du Bois Reymond's Archiv f. Physiologie," 1890, p. 280; Ewald and Boas, "Virchow's Archiv," 101, pp. 325, 375.

Uffelmann's Test.—Lactic acid is recognized by its effect upon a very dilute, almost colorless, solution of neutral ferric chlorid, which is converted into a canary-yellow color by its action. This is Uffelmann's test. It is rendered more certain if the solution is made by adding carbolic acid to the iron solution until it assumes an amethyst-blue color. To 10 c. c. (2 1-2 fluid drams) of two to five per cent. solution of carbolic acid the iron solution may be added until the proper tint is attained. A few drops of even a 0.05 per mille solution of lactic acid (1 to 20,000) will change the blue to the distinctive yellow color.

There are, however, sources of error. The lactates cause the same reaction, but this matters not, because we desire to recognize the lactic acid, whether in combination or not. The reaction, however, takes place with alcohol, sugar, and certain salts, especially phosphates, which are often found in gastric contents. The color produced by phosphates is not identical, but if the filtrate operated with has a yellow tinge the resulting color may approximate it very closely. Under these circumstances the lactic acid must be extracted with ether. Two to five c. c. (1-2 to 1 1-2 fluid drams) of the stomach contents are thoroughly shaken with three or four times the amount of ether. The ether is allowed to rise to the top, which it does rapidly, and is then poured off into a glass beaker. More ether is added and the washing repeated until in all about one fluid ounce (30 c. c.) of ether has been used. The ether is then evaporated by placing the beaker, with its contents, in a vessel of hot water. The residue is redissolved in a few drops of water and *one* or *two* drops of Uffelmann's reagent allowed to fall from a pipette into the solution. Too much of the solution may mask the reaction.

The *fatty acids*, especially *butyric*, strike a tawny yellow color with a reddish tinge with Uffelmann's chlorid of iron solution, but 0.5 per 1000 or 1 to 2000 is required before the reaction occurs.

Fatty acids may also be detected by heating to the boiling-point a few cubic centimeters of the gastric filtrate in a test-tube over the mouth of which a strip of moistened neutral or blue litmus paper is placed. On this the vaporized acid will produce the usual change.

The oily particles of pure *fat* may be recognized floating in the gastric contents or in the aqueous solution of the residue after evaporating the ethereal extract. Butyric acid may also be separated, in the form of drops by adding small pieces of calcium chlorid.

Acetic acid is easily recognized by its odor, but it may also be detected by neutralizing with sodium carbonate the watery residue after the removal of the ethereal extract, and then adding neutral ferric chlorid solution. A striking blood-red color appears, also produced by formic acid, but this is never a constituent of gastric contents.

Alcohol, which is sometimes formed in the stomach in intense yeast fermentation, may be detected by Lieben's iodoform test applied to the distillate of the stomach contents, as follows: To a portion of the distillate add a small quantity of liquor potassæ, then a few drops of a solution of iodine and iodid of potassium (1, 2, 50). If alcohol be present, a yellowish precipitate of iodoform takes place slowly, which may also be recognized by its odor. The same precipitate occurs with acetone, but rapidly.

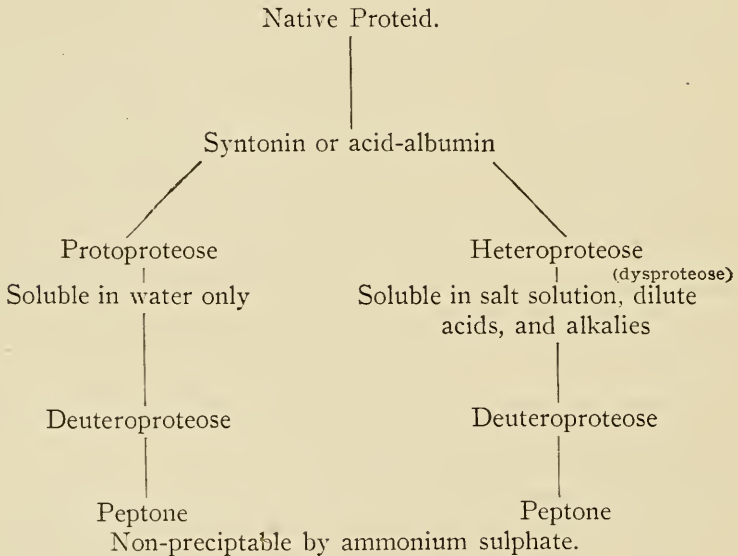

Examination of Products of Albumin Digestion.—The term *proteolysis* is applied to albumin digestion, in which, if complete, all proteid food-stuffs are converted into soluble and diffusible peptone. It takes place partly in the stomach through the agency of pepsin-hydrochloric acid, but probably

even to a greater degree in the small intestine, by the action of trypsin, the pancreatic digestive ferment. In this process the first step is the production of certain substances intermediate between albumin and peptone. Those which are of chief importance in the study of gastric digestion are syntonin or acid albumin and the so-called proteoses* or albumoses. In the ordinary process of digestion, with a normal gastric juice, some or all of these substances should be at some time present. So far as they are the products of gastric digestion, they may be studied by the aid of a test meal and removal of the gastric contents, as already described.

The products of pepsin proteolysis may, in a general way, be divided into three groups:

1. Those precipitated by neutralization and represented mainly by syntonin or acid albumin.
2. Those precipitated by saturation of the neutralized fluid with ammonium sulphate and represented by the proteoses.
3. Those non-precipitable by ammonium sulphate and represented by what is commonly known as peptone.

The relation of these products to each other is shown by the following diagram, proposed by Neumiester:

Proto- and hetero-proteoses are primary bodies formed directly from the initial product syntonin by the further action of the ferment. Again, deuteroproteose is a secondary proteid, being formed by the further hydration of the primary body. Finally, peptone, the ultimate product of pepsinproteolysis, is the result of the hydration and possible cleavage of deuteroproteosis. The two primary proteoses differ from each other more particularly in that protoproteose is readily soluble in water alone, while heteroproteose is soluble only in salt solution, dilute acids, and alkalis.

To Separate Proteoses (Propeptone) and Peptone.—Take two or three c. c. of the stomach filtrate and remove any acid albumin or syntonin by neutralization and filtration. The proteoses and peptones remain in solution.

* The so-called propeptone or hemialbumose is a mixture of proteoses.

To a portion of the filtrate apply the biuret test—viz., one c. c. of liquor potassæ and a few drops of a one per cent. solution of cupric sulphate. A purple-red color indicates the presence of proteoses and peptone.

Another portion of the neutral filtrate is then treated with an equal quantity of a saturated solution of sodium chlorid and one or two drops of strong acetic acid added. Proteoses, if present, are precipitated, and may be filtered out. To the filtrate again apply the biuret test. A purple-red color indicates the presence of peptone, and its quantity may be approximately estimated by the intensity of the reaction, provided we always use the same proportion of stomach contents, solution of potash, and cupric sulphate. Should it happen that a handsome biuret reaction is struck before removing the proteose, or but a faint one or none at all afterward, the proportion of proteose is large and peptone small. Cahn has shown that in dogs, at least, the quantity of peptone remains at a certain percentage, being probably kept at that figure by its removal as formed. Hence, the only index of the rapidity and extent of albumin transformation is the amount of proteose formed or remaining. Finally, Ewald, Gunlich, and R. A. Chittenden conclude that the formation of true peptone in the human stomach is small. It is true, peptone may be found in relatively large amount, but a quantitative estimation of the proteoses and peptone always shows the former to be in excess. Gastric digestion is rather, therefore, to be considered as a preliminary step in proteolysis, and is preparatory to the more thorough office of pancreatic digestion.

To Estimate the Activity of Proteolysis, or Albumin Digestion.—By Ewald's method, coagulated white of egg is cut into thin slices and out of these small discs are cut by a cork-borer or similar instrument. These may be prepared in quantity and kept for use in glycerin, which should, however, be washed off before using. An equal quantity of the filtered gastric fluid is placed in four small test-tubes and one or two discs of albumin put into each. To the first nothing else is added; to the second, enough hydrochloric acid to make a solution of about * 0.3 to 0.5 per cent. This is accomplished by adding two drops of hydrochloric acid to 90 minims (5 c. c.) of stomach contents. To the third is added a definite quantity of pepsin, about 3 to 7 1-2 grains (0.2 to 0.5 gm.); to the fourth, both hydrochloric acid and pepsin.

The test-tubes are placed in an incubator at about 100° F. (37.8° C.) and from time to time examined with a view to learning how far the liquefaction of the discs of albumin has proceeded. The rate of this will inform us whether digestion would have occurred without the addition of anything, or whether acid or pepsin or both were necessary. We will learn, also, whether by adding more hydrochloric acid we have made the acidity excessive.

It must be remembered, however, that after the peptone has reached a certain percentage its further production is retarded, or even suspended, so that there may be an apparently slow reaction with even a very active gastric juice. Ewald correctly reminds us that all laboratory attempts to imitate digestion are defective in the important respect that with our test-tubes and flasks we can neither imitate absorption on the one hand, nor, on the other, allow for the onward movement to the intestines of the gastric contents, two important functions by which the stomach strives to maintain a fairly uniform degree of concentration of its contents.

* The difference between the strength of the acetic acid of the German pharmacopœia (25 per cent. of the anhydrous acid), intended by Ewald, and that of the U. S. P. (32 per cent.) is not sufficient to necessitate a change of proportion.

The Action of Rennet, or Lab-ferment, the Milk-coagulating Element of the Natural Gastric Juice.—The simplest method of estimating the action of rennet is that of Leo. To 10 c. c. (3.6 fluid drams) of *raw* milk are added two to five drops of stomach contents. Raw milk is used because it coagulates ten times more rapidly than boiled milk, while neutralization is unnecessary because of the relatively small quantity of gastric juice used. The mixture is placed in the warm chamber at 100° F. (37.8° C.), and coagulation should take place in from one minute to several hours. The characteristic coagulating of rennet is a cake of casein floating in clear serum, while acids produce lumpy and flaky masses.

The rennet-ferment, or enzyme, does not exist primarily as such, but as a rennet-zymogen or proenzyme, which itself has no action on milk, but is converted into rennet by the action of any acid, as hydrochloric, or of warm chlorid of calcium. This may be shown as follows: If the spontaneous coagulating action of gastric juice or milk be destroyed by neutralization by an alkaline carbonate, this property may be restored by digesting with dilute hydrochloric acid, or by the addition of a five per cent. solution of calcium chlorid. While fasting, and at the beginning of digestion, zymogen only is present in the stomach, but, later, both it and the ferment are found. An acid reaction for the curdling action of rennet is not absolutely necessary. As pepsin and rennet usually accompany each other the presence of one may be inferred from the presence of the other.

Digestion of Starch and Sugar.—It is well known that during digestion starch is converted into grape sugar, and cane sugar is converted into *invert* sugar—a mixture of cane and grape sugar. This action, commenced in the mouth by the ptyalin of saliva, is continued to a less degree in the stomach so long as the acidity is slight (0.01 per cent. for HCl, 0.1 or 0.2 per cent. for lactic, 0.4 per cent. for butyric), and is finished in the small intestine by the trypsin (amylolypsin) of the pancreatic juice. As in albumin digestion, there are intermediate substances between albumin and peptone, so between starch and grape sugar there are similar intermediate products. The order is as follows:

1. Starch. 2. Dextrins (Erythroöextrin, Achroöextrin). 3. Maltose.
4. Dextrose, or grape sugar.

Starch is recognized by the deep blue color struck with iodine or Lugol's solution (iodine 1, iodid of potassium 2, distilled water 200), and the reaction grows less vivid as the starch is converted. Of the dextrins, erythroöextrin strikes not a blue, but a purple color, while solutions of achroöextrin, maltose, and grape sugar take on only the yellow color of the iodine solution. Where a mixture of these substances occurs, the first few drops of the iodine solution produce no color at all, or only a transitory one, being taken up by the dextrose and maltose, while the addition of more iodine strikes the purple of erythroöextrin or the blue of starch.

If, therefore, amylaceous transformation has progressed normally in the mouth and stomach, so much starch should be changed into achroöextrin, maltose, or dextrose that the addition of small quantities of Lugol's solution does not strike the characteristic color. If, however, the blue or purple reactions appear, conversion has not been sufficiently rapid into maltose, the principal product of gastric conversion, the change into dextrose being completed in the small intestine. This may be due either to a deficiency of ptyalin or a too rapid production of acid in the stomach. From such event we might also infer a hyperacidity of the gastric juice.

To Determine the Rate of Absorption from the Stomach.—Penzoldt's and Faber's method is that generally followed. A capsule containing iodid of potassium, 0.1 gm. (1 1-2 grains), is swallowed, being first carefully wiped to remove any adherent particles. The appearance of the iodid in the saliva indicates that absorption has taken place from the stomach. To determine this, starch paper is first prepared by moistening with starch paste and drying. Then, after the salt is swallowed, a piece of the paper is moistened every five minutes with the saliva, and the moistened spot touched with fuming nitric acid. As soon as the iodine appears in the saliva the characteristic blue reaction is struck.

When absorption is normal, this reaction usually takes place in *ten or fifteen minutes*, but when absorption is abnormally delayed, the reaction is also delayed half an hour or more, or it may not occur at all.

To Test the Motor Function of the Stomach.—Three methods are practiced. In v. Leube's method the gastric contents are withdrawn six to seven hours after the ingestion of a large meal, or two and a half hours after an Ewald's breakfast. There should be no solid residue. The more suitable meal for this purpose is the larger one given on page 333.

In a second method, suggested by Ewald and Sievers, salol is administered, and the products of its lysis are sought for in the urine. This, though not without drawbacks, is preferred. Salol is composed of phenol and salicylic acid, into which it is broken up by the action of the pancreatic juice, but not by the acid gastric contents. Salicyluric acid, a product of decomposition of salicylic acid, appears in the urine *forty to sixty*, or at most *seventy-five, minutes* after taking 15 grains (1 gm.) of salol when gastric peristalsis is normal. Salicyluric acid is readily detected in the urine by the violet color produced on the addition of neutral ferric chlorid solution. The method employed is to place a drop of urine on a piece of filter-paper and bring in contact with this a drop of a ten per cent. ferric chlorid solution. The edge of the drop will strike a violet color in the presence of a mere trace of salicyluric acid. Decomposition of salol may be delayed by extreme acidity of the gastric contents as discharged into the duodenum. Practically this is not a serious drawback, tolerably constant results being obtained. To meet it, however, Huber suggested that the outside limit of excretion of salicyluric acid be determined—that is the point noted when salicyluric acid fails to appear in the urine after the ingestion of 15 grains (1 gm.) of salol. This should occur at the end of twenty-four to thirty hours. If, therefore, it continues after this, peristalsis must be slow.

A third test of the motor function is Klemperer's oil test, in which 100 c. c. (3 1-2 ounces) of olive oil are introduced into the stomach by the tube after the organ is thoroughly washed out. Two hours later the stomach is aspirated, and if there is motor sufficiency, there should be a very small residue, not more than 20 to 40 c. c. If any decided quantity above this remain, it is fair to conclude that peristalsis is slow.*

* Max Einhorn (Article "Diseases of the Stomach," in "Twentieth Century Practice of Medicine," vol. viii., 1896) divides motor function of the stomach into two parts—viz., that consisting in the transportation of the stomach contents into the smaller intestine, which he calls *prochoresis* (ἡ προχώρησις, advancing), and that consisting in merely mechanical motion to which the ingesta are subjected within the organ, which he calls *akinesis* (ἡ ακίνησις, shaking). The former is tested in the manner described; the latter, by a mechanical appliance connected with a battery,—the whole too complex for introduction here.

ACUTE CATARRHAL GASTRITIS.

SYNONYMS.—*Acute Gastric Catarrh; Acute Dyspepsia; Gastric Fever.*

Definition.—Acute inflammation of the stomach, of moderate intensity, due to simple non-specific irritation or to irritation from the products of decomposing and fermenting foods.

Etiology.—This form of inflammation occurs at all ages, and is often due to the irritant effect of indigestible food or food in a state of incipient decay and fermentation. Simply overloading the stomach, even though the food be wholesome, may be a sufficient cause. The introduction of large quantities of strong alcoholic drinks, as often happens in a debauch, is one of the most common causes of acute gastritis of the simple variety. The susceptibility of different individuals and of different families to the foregoing causes of irritation varies greatly.

Morbid Anatomy.—A more or less uniform coating of the stomach with mucus is the most constant feature of simple acute gastritis, and justifies for it the name, gastric catarrh. The removal of this mucous coating reveals a hyperemic redness, which in the highest degrees may be associated with punctiform hemorrhages and hemorrhagic erosions. The mucous membrane is swollen and edematous, and minute examination recognizes numerous mucus-laden cylinder cells, which have been extruded from the mucus-glands everywhere present, while even the peptic gland cells are cloudy and granular.

Symptoms.—These are a natural sequence of the morbid state. A *want of appetite* and *loathing of food*, *nausea*, more rarely *pain*—these are the more constant subjective symptoms. To them may be added an *unpleasant taste* in the mouth, sometimes bitter, sometimes metallic, a *pasty* sensation of dryness, and even *thirst*, a sense of *fullness in the head* rather than headache, and *dizziness*, and often extreme *mental depression*.

Objective symptoms are *epigastric distention*, more rarely *tenderness*, a *coated tongue*, *dryness* of the *lips*, rarely *herpes*, a *heavy breath*, acid or bitter *eructations*, sometimes a scanty secretion, at others an excess of saliva, finally *retching* and *vomiting* with greater or less relief. The *bowels* are constipated, though sometimes there is diarrhea. *Jaundice* is occasionally present, and indicates that the inflammation extends into the duodenum and produces obstruction of the common bile-duct. There may be slight *fever*, sometimes decided, with a temperature of 101° F. (38.3° C.), or slightly more, and a corresponding pulse. On the other hand, the pulse is not infrequently slowed below the normal, being inhibited by the gastric irritation. The *urine* is "feverish," scanty, and high colored, with a corresponding specific gravity and a tendency to deposit urates. Most cases are without febrile symptoms. Indeed, v. Leube says that in a few instances only is fever the result of acute gastric catarrh, and that when the two are associated, the gastric catarrh is rather the result of some acute febrile process, as, for example, one of the infectious fevers. It has occasionally happened that gastritis has been ushered in with a *chill*.

Gastric Contents.—The vomited matter and gastric contents removed after a *test meal* are deficient in hydrochloric acid, but contain an excess of mucus, lactic and fatty acids, and more than the normal residue of undigested food. Digestion is prolonged, the stomach-washings exhibiting a

considerable amount of undigested food seven hours after the ingestion of a test meal. Indeed, it often happens that in from twelve to twenty-four hours after the beginning of such an attack large quantities of undigested food are vomited in much the same condition in which they were swallowed.

Diagnosis.—This is not usually difficult, except in the case of the febrile form. In this form, especially when the disease has been ushered in with chill, it is sometimes difficult to decide between it and some one of the infectious fevers, but a few days' waiting will soon remove the doubt by the appearance in the latter of eruptions or other distinctive symptoms. The presence of a cause sufficient to excite gastric inflammation will add to the probability of the presence of acute catarrhal gastritis.

Prognosis.—This is invariably favorable in cases of true simple gastritis.

Treatment.—Many mild cases recover spontaneously, if let alone and if all food is withdrawn for twenty-four hours. The symptoms gradually subside and the patient recovers. In a few cases where there is evidently retained food, an *emetic* will give relief; in all, a brisk *saline purge* is helpful. A bottle of cold solution of citrate of magnesium in divided doses, say a fourth every half hour, is one of the most agreeable and efficient aperients to relieve the congestion and the symptoms. Or some one of the *natural aperient waters*, such as Hunyadi Janos or Friedrichshalle, Apenta, Rubainat, Veronica, or Carlsbad, may be substituted. If there be great sensitiveness of the stomach, small doses of calomel, frequently repeated, say 1-6 to 1-4 grain (0.011 to 0.016 gm.) every hour, may be substituted, or 7 1-2 to 10 grains (0.5 to 0.666 gm.) may be given in one dose. In either event a saline should be given sooner or later, as in this way is secured copious depletion of the upper alimentary canal. The *alkaline mineral waters*, represented by the Vichy, Vals, and Contrexville waters in France, but which have unfortunately no equivalent in any of the natural mineral waters of this country, are admirable adjuvants, since they aid in clearing the stomach of mucous secretion and in producing osmosis. The saline mineral waters represented by the well-known Saratoga waters of this country are also efficient, more especially by their aperient qualities.

CHRONIC CATARRHAL GASTRITIS.

SYNONYMS.—*Chronic Gastric Catarrh; Chronic Catarrhal Dyspepsia.*

Definition.—A condition of chronic hyperemia, associated with excessive mucus-secretion and deranged gastric juice formation, with ultimate structural changes in the mucosa.

Etiology.—Any cause which will produce continuous moderate irritation of the mucous membrane of the stomach is capable of producing chronic catarrhal gastritis. The immoderate use of alcohol is probably the most frequent of these causes, but constant overeating is also a common cause, especially rapid eating.

Very frequently, too, chronic gastritis is secondary to primary disease elsewhere, and especially mitral disease of the heart and interstitial hepatitis. Both of these affections cause a passive congestion of the stomach, which ultimately produces the lesions characteristic of chronic gastritis. Thrombosis of the portal vein acts similarly. Chronic pulmonary disease, and even

diseases of the pleura impeding the circulation in the lungs, produce similar effects through stasis. A predisposition exists in certain families to chronic gastric catarrh.

Morbid Anatomy.—The fundamental condition is a hyperemic swelling of the gastric mucosa. This is favored by the superficial situation of the venous plexus about the mouths of the gastric glands as contrasted with the deep-seated position of the arterial network around their bases, by the thinness and compressibility of the venous walls, and by the sluggishness of circulation necessitated by the peculiar secretory function of the stomach. The hyperemic surface is, however, more or less obscured by a tough yellowish-white covering, made up of mucus and emigrant pus-cells. The changes are more marked at the pyloric end.

These may constitute the sum of changes, but in more chronic cases minute examination reveals a varying degree of hyperplasia of the connective tissue, and even of the mucous glands, which exhibit in places an atypical branching, like the fingers of a glove. The tubules are distended by secretion in some places, and in others stenosed by the contraction of the overgrown connective tissue surrounding them. The hyperplastic process may result in *plication* of the mucous membrane, such as is natural at the pyloric end, and lead finally to the *mammillated stomach* by atrophy and contraction of certain portions, and to more pronounced swelling of the remaining parts. An ultimate result is sometimes the rare condition known as *polyposis ventriculi*. Atrophy of the mucous membrane may be extensive, and even almost total.

Symptoms.—These naturally result from the morbid state. The mucous membrane is bathed with *mucus*. The *gastric juice* is *imperfect* in quality and quantity. Especially is the hydrochloric acid deficient. Digestion is therefore imperfect, the residue of ingested food undergoes fermentation and decomposition, generating lactic, acetic, and butyric acids and alcohol. Peristalsis is delayed because of the absence of its natural stimulus, and thence follows a further retention of food in the stomach. The natural consequence of such morbid changes is *loss of appetite* and even *disgust for food*, an unpleasant *taste*, a *pasty sensation in the mouth*, a *coated tongue*, and *discomfort after taking food*, including *nausea*, often *vomiting*, sometimes immediately, sometimes an hour or two after taking food. The vomitus consists of undigested food, usually mixed with a large amount of mucus. Its reaction may be neutral or acid, sometimes even acridly so, but the acidity is not due to hydrochloric acid, which is diminished, but to the organic acids generated in fermentation.

To these symptoms may be added *headache*, or a dull, unpleasant feeling in the head, *vertigo*, *disturbed sleep*, *depression of spirits*, a sense of weakness and disgust with life. Very disagreeable is the *distention* and sense of fullness in the epigastrium, causing even *pain*, which adds further to existing discomforts. There may be *tenderness*, but it is diffuse, and not circumscribed. There is usually *constipation*, while the urine may be scanty. Reflected symptoms are *palpitation*; *frequent, slow, or irregular pulse*; shortness of breath. There is no fever. *Cough*—the so-called “stomach cough”—is sometimes present, but more frequently what is called by the patient stomach cough is the cough of tubercular phthisis, which the sanguine patient easily convinces himself is due to stomach derangement.

Gastric Contents.—Analysis of the gastric contents, withdrawn after a test meal, shows a similar deficiency of pepsin as well as of hydrochloric acid,

while the other tests described discover retarded peristalsis and delayed absorption. Occasionally there is a little blood present, and frequently fungi, especially yeast-spores and sarcinæ ventriculi.

Should the disease progress to total atrophy, the gastric contents, after a test meal, may even be devoid of mucus as well as of free and combined hydrochloric acid, and pepsin, blood, and epithelium, may be made up mainly of undigested food, with bacteria and a few round cells. Repeated examinations of stomach contents, after a test meal, may be necessary before a confident knowledge of its features can be arrived at.

Diagnosis.—With the symptoms detailed, and the altered state of the secretory, absorptive, and motor functions of the stomach, ascertained as directed, there is usually no difficulty in diagnosing a condition of chronic gastric catarrh. It is to be remembered, however, that chronic gastric catarrh may accompany ulcer and carcinoma of the stomach, in which the otherwise distinctive symptoms of the former are obscured, while with the exception of tumor and occasional coffee-grounds vomit the symptoms of carcinoma may not differ from those of chronic gastric catarrh, hydrochloric acid and pepsin being deficient in both. Dilatation of the stomach is also accompanied with symptoms of gastric catarrh, including even the clinical characters of the gastric juice, and careful examination must always be made for the physical signs of dilatation.

Prognosis.—The prognosis and treatment will depend upon the etiology. If the chronic gastric catarrh is a result of chronic cardiac or hepatic disease, it is curable only so far as these affections are curable, and is relieved as these are relieved. Careful physical examination is always necessary in each case, that obscure cases may be recognized.

Chronic gastric catarrh not the result of organic heart or pulmonary or liver disease, and which has not already resulted in atrophy of the mucous membrane, may be cured by careful and persevering treatment. If there be extensive atrophy of the gastric mucous membrane, a proper assimilation of food becomes impossible, and the symptoms of anemia are ultimately added. Their close resemblance to those of pernicious anemia has been pointed out, while an essential cause of pernicious anemia has been held to be gastric atrophy, in evidence of which a case of William Osler and Frederick P. Henry is often quoted.

Treatment.—The treatment of chronic gastric catarrh caused by chronic liver or heart disease is largely that of these affections, but the treatment useful in the ordinary primary forms of the disease may be with advantage associated with that of the more chronic affection.

A successful treatment of catarrhal dyspepsia requires considerable patience, but if the diagnosis be correctly made and the cause removed, the patient may be promised a cure in time. Of primary importance is the *elimination of the cause*, whether it be alcohol or injudicious eating. Simple, wholesome, and properly cooked food, thoroughly masticated and slowly taken, should be the rule of every life, and the simple forms of the disease may sometimes be cured by a return to such a habit, especially if a proper action of the bowels is also habitually secured.

It is not easy to select a *diet* which will suit every case, and after the injunction that articles evidently difficult of digestion, such as pastry, oils, and fats, are to be excluded, it is often sufficient, and even necessary, to leave the choice of special articles to the patient, with the direction to discard what his experience teaches is harmful. Often, however, the patient cannot be

trusted to do this, while the moral effect of specific directions is good, but even then our bill of fare must often be tentative. The measures by which the *regular habit of bowel movement* is brought about must vary with circumstances, but when it is remembered that we have to deal with a congested mucous membrane, it is plain why the salines which deplete the upper alimentary canal are so efficient, especially when associated with mercurials. Among these are the numerous natural aperient waters, such as Friedrichshalle, Hunyadi Janos, Apenta, Carlsbad waters, and our own Saratoga and Bedford waters, all of which are said, in common parlance, to act upon the liver, though, in fact, they simply deplete the alimentary canal. The useful effect of these waters is so often availed of to remove the uncomfortable effect of a debauch in eating that their use is abused. No remedies are, however, so useful when needed, and the fact that almost any of them can be taken before breakfast, securing an effect after that meal, makes them doubly convenient. A fit substitute for the water, especially when traveling, is the Carlsbad Sprudel Salt, obtained by evaporating the Carlsbad water. Carlsbad salt, of which the dose is usually a teaspoonful, is best taken in a glass of hot water. An artificial Carlsbad salt may be made as follows: Sodium sulphate, 50 parts; sodium bicarbonate, 6; sodium chlorid, 3. The dose is a teaspoonful dissolved in half a glass to a glass of water. The natural waters are, however, to be preferred, if they can be obtained.

The occasional associated treatment by mercurials, especially blue mass, in doses of three to ten grains (0.2 to 0.66 gm.) the evening previous, sometimes adds to the efficiency of the salines. Calomel may be substituted in doses of five to ten grains (0.33 to 0.66 gm.), with as much sodium carbonate. If there be nausea, calomel may be given in smaller doses, say 1-10 to 1-5 grain (0.0011 to 0.0132 gm.) hourly. Podophyllin may be substituted for the mercurials or added to them in doses of 1-10 to 1-4 grain (0.006 to 0.06 gm.). *Cascara sagrada* is one of the most valuable of aperients. The best preparations are the solid and fluid extracts. The former may be given in two-grain doses (0.132 gm.) in a pill after dinner and after supper. The fluid extract, in 15- or 20-minim (1 to 1.3 gm.) doses, can be given in the same manner, but the dose of each must be modified to suit the requirements of individual cases. In lieu of the saline aperients before breakfast, a glass of hot water alone, slowly sipped while dressing, is often useful and tends to relieve the morning sickness that sometimes attends chronic gastric catarrh. It probably liquefies the mucus and washes it away into the duodenum.

As to medicines intended to aid digestion, the most efficient is *hydrochloric acid*, which may sometimes be replaced by nitro-muriatic acid. It seems now definitely settled that hydrochloric is the acid to which the gastric juice owes its efficiency, and as well settled that it is diminished in chronic gastric catarrh. Another very important rôle is, however, assigned to hydrochloric acid, viz., an antiseptic effect, in checking the multiplication of pathogenic bacteria—bacteria of fermentation and decomposition—which are continually introduced with the food into the stomach. A third rôle performed by hydrochloric acid is the conversion of the granular pepsinogen in the protoplasm of the peptic cells into the enzyme, pepsin. Its scantiness, therefore, not only impairs the activity of the gastric juice, but also favors the acetic and lactic acid fermentations, the products of which keep up irritation. On the other hand, *pepsin* is seldom abnormally scanty, because so little is required for its purpose. As it does no harm, however, it may with propriety be administered with hydrochloric acid. The latter has, heretofore,

been administered in too small doses.* Not less than 15 minims (1 gm.) of the dilute acid should be given, and from 30 to 60 minims (2 to 4 gm.) are sometimes required. It should be given, further diluted, fifteen minutes after a meal, through a glass tube carried back into the fauces, not merely to save the teeth, but also to avoid the unpleasant taste. The pepsin should be given in solution with the hydrochloric acid in doses of five to ten grains (0.33 to 0.66 gm.). The wine of pepsin has always been a favorite preparation with me, notwithstanding the small proportion of pepsin contained in it. I have been in the habit of combining it with nitro-muriatic acid rather than with hydrochloric, and not infrequently adding 1-30 grain (0.002 gm.) of strychnin to each dose of 1-2 ounce (15 c. c.) or two fluid drams (7.5 c. c.) of the wine.

Trypsin or pancreatin is also much used. It is commonly prescribed in the tablet form, five grains (0.33 gm.) at a dose, sometimes keratin coated, that it may not be dissolved until it passes into the small intestine, where alone in the presence of an alkali it is capable of acting.

It is usual also to employ the *bitter tonics* in the treatment of this form of dyspepsia, including gentian, quassia, columbo, angostura, cardamom, and nux vomica. They are supposed to stimulate the secretion of gastric juice, and should be taken immediately before meals or with food. A moderate amount of alcohol in the shape of a little whisky with water during meals or a glass of dry sherry is often serviceable, but care should be taken in the use of alcohol lest a habit be contracted. The persons to whom it is advised should be well selected, and it should not be recommended to the young. *Stimulating condiments*, such as red pepper and mustard, often give temporary relief, but they ultimately aggravate the local congestion and should be forbidden. *Common salt*, on the other hand, is a rational adjuvant, furnishing chlorin for the formation of hydrochloric acid.

Nitrate of silver is also a useful drug in cases of chronic gastric catarrh, in doses of 1-4 grain (0.0165 gm.) fifteen minutes to half an hour before meals, dissolved in a quarter of a glass of water. I have never found *bismuth* of much use in this form of dyspepsia. In fact, its tendency to produce constipation is a contra-indication to its use. Where there is acidity it may be useful, as may also be sodium bicarbonate and mint, but it is better, if possible, to strike at the root of the evil by preventing the fermentations which produce the flatulence and acid.

In obstinate cases the *milk treatment* may be resorted to with advantage, and should be carried out with skimmed milk or whole milk diluted with water or Vichy. The efficiency of the milk treatment is largely due to the fact that the quantity of food taken is greatly reduced. Not more than two ounces should be given at first, every two hours, the quantity increased only as the hunger of the patient demands more. There will be at first a loss of weight, but this is again recovered with the increase in quantity. Having secured a tolerance for milk, of which from three to five pints (1 1-2 to 2 1-2 liters) are required in twenty-four hours, the interval may be prolonged and other articles of food cautiously added—a little bread and butter, an egg, a chop, or a small piece of steak, broiled. Gradually the simpler vegetables, such as rice and potatoes, may be added, then weak tea and coffee cautiously, the effect of each article being carefully watched. If flatu-

* Since 4.5 liters (9 pints) of 0.2 per cent. solution of HCl are required to saturate 100 gm. (about 3 oz.) of dry fibrin, and this amount of acid utilized in combining with the albumin leaves none apparent as free HCl, it is plain why the small doses often prescribed are insufficient,

lence is caused by the farinacea and sugars, they should be withdrawn. *Hot bread* and *fats* will rarely ever be permissible to such patients. The same may be said of *ice-cream* and *iced water* with meals, though a moderate amount may be permitted between meals, especially of iced water. Ripe *fruits*, on the other hand, are very desirable foods and should be allowed tentatively.

In bad cases of chronic gastric catarrh *lavage* is one of the most useful measures. Not only does it wash away the coating of mucus which is at once a hindrance to the secretion of the gastric juice and a cause of nauseous discomfort to the patient, but it also stimulates glandular activity. It should be done in the morning before breakfast, with the stomach tube already described, with funnel attachment. Simple water as hot as can be borne, may suffice, or if there be much mucus, a two per cent. solution of sodium bicarbonate or Carlsbad salt, or a one per cent. solution of sodium chlorid may be used. If antiseptic fluids are indicated, a two per cent. solution of resorcin may be substituted, or a one per cent. solution of salicylic acid.

The stomach tube having been introduced, as directed on page 333, the tepid water or solution employed is run in slowly and removed by siphonage,

Fig. 29.—Leube-Rosenthal Arrangement for Auto-lavage.

the outer end of the tube being lowered for the latter purpose. This process is repeated until the stomach is thoroughly washed out. Auto-lavage is easily practiced by the patient himself by means of the apparatus illustrated in the text.

It is in these cases, too, that a course at Carlsbad is very efficient, and remarkable cures are reported. Here, too, the restricted dietary and depletion of the upper alimentary canal by the natural mineral waters are the bene-

fitting agents. Similar courses are carried out at Kissengen, Wiesbaden, and Ems, but, unfortunately, we have no such places in America. Saratoga fulfills the conditions so far as an aperient water is concerned, but the majority of persons who go to Saratoga continue eating and drinking as at home. Finally, the habitual use between meals of the alkaline mineral waters alluded to—viz., Vichy, Vals, and Contrexville—is undoubtedly useful, relieving and averting gastric catarrh.

PHLEGMONOUS OR SUPPURATIVE GASTRITIS.

Definition.—A rare form of gastritis, in which there is diffuse purulent infiltration of the submucosa, but sometimes also circumscribed abscess, causing a possibly detectable tumor in the gastric region, a tumor which disappears if the abscess ruptures.

Etiology.—Phlegmonous gastritis is a result of infectious processes, among which have been puerperal fever and other forms of pyemia. It has been found associated with peritonitis and trauma. In more cases a cause is not discoverable. It has been met more frequently in men than in women.

Symptoms and Diagnosis.—Epigastric pain and tenderness, general abdominal pain and tympany, vomiting, diarrhea, fever, delirium, dry tongue, small, frequent pulse, coma, collapse, and death—symptoms that closely resemble those of peritonitis, with which, as has been said, it is sometimes associated—are those met in phlegmonous gastritis. The vomited matter very rarely contains pus. It is plain, therefore, that these symptoms, associated with an infectious process, can only give rise to suspicion that the disease is present, since the same symptoms may be caused by peritonitis. Even the vomiting of pus is not diagnostic, because pus may arise from other sources between the mouth and stomach. The presence of a tumor which subsides after vomiting of pus furnishes better ground for suspicion, though vomited pus may also come from an abscess in the vicinity of the stomach which has ruptured into that organ.

Treatment.—This can only be symptomatic, as nothing can be done to avert a termination which is invariably fatal.

TRAUMATIC AND TOXIC GASTRITIS.

Definition.—An inflammation of the stomach caused by the ingestion of corrosive poisons, such as the strong mineral or organic acids, caustic alkalis, phosphorus, arsenic, corrosive sublimate, and the like.

Morbid Anatomy.—The appearance differs a good deal, according to the degree of irritation. In extreme degrees, such as are produced by the strongest acids and alkalies, the mucous membrane is disintegrated, shreddy, and may be converted into a black eschar, the borders of which are lighted up with intense inflammation. In milder forms, such as are produced by phosphorus, arsenic, and strong alcohol, there are cloudy swelling and fatty degeneration of the gastric gland cells and vessel-walls, producing ulceration and hemorrhagic extravasation. The fury of the irritation is expended on the fundus, as the part first reached, and its ravages become less extensive as the pylorus is approached.

Symptoms.—These also vary with the degree of irritation, but there are always *intense burning pain, tenderness on pressure, thirst, and vomiting* of blood and even of fragments of mucous membrane. To these are added, in severe cases, *small, frequent pulse, cold sweat, and collapse*. These latter symptoms point to peritonitis, a very frequent complication, the direct result of the deep-seated action of the irritant. If the patient does not perish promptly, *symptoms indicating blood dyscrasia* supervene, including albuminuria, hematuria, jaundice, subcutaneous blood extravasations, and the like. When recovery takes place or death is long delayed, varying areas of mucous membrane may be replaced by *cicatricial tissue*, and there may be subsequent contraction and distortion.

Diagnosis.—This is based on a knowledge that the patient has swallowed a corrosive poison. In the absence of this knowledge the odor of the breath may suggest the cause, and evidences of corrosive action in the mouth and pharynx often disclose unfailing signs.

Prognosis.—This varies with the degree of lesion. The gastritis caused by the powerful corrosive poisons is always fatal. The lesser degrees may be followed by recovery.

Treatment.—This consists, first, in the use of chemical opposites, as vinegar and other weak acids for alkalies and alkalies for acids. The antidotes called for by special substances are freshly prepared ferric hydrate for arsenic, lime-water for oxalic acid, cold water and ice after the specific action of the poison has been counteracted, and ice externally to the abdominal walls. These should be followed by the free use of diluents and demulcents, of which the various mucilages and milk are examples. (See concluding section of book on the Treatment of Poisons.)

Diphtheritic Gastritis.—This occurs sometimes as an extension from faucial or laryngeal diphtheria, but more frequently it is secondary to typhus or typhoid fever, smallpox, scarlet fever, pneumonia, and sometimes primarily in weak children. There is no way to recognize such condition during life.

Mycotic Gastritis.—It is very doubtful how far fungi can cause inflammation of the stomach. The bacteria which flourish in the mouth are destroyed by the acid gastric juice, while the fungi that thrive in acid fluids, such as the yeast fungus, the penicilium, and the sarcina, are probably accidental results of the retention of the gastric contents beyond the natural time and are not harmful. The possibility of their producing noxious results cannot, however, be denied. Ulceration has even been ascribed to them. On the other hand, the larvæ of certain insects must also be acknowledged as possible causes of inflammation.

NERVOUS DYSPEPSIA.

SYNONYM.—*Gastric Neurasthenia.*

Definition.—A form of dyspepsia due to nervous influence, in which, notwithstanding the presence of a train of annoying symptoms, the act of digestion is completely accomplished within the normal time of seven hours, and seven hours after an ordinary dinner the stomach is free from residue.

Etiology.—The nervous temperament and feminine gender predispose to nervous dyspepsia. Any cause that develops an overexcitability of the nervous system may become a factor of nervous dyspepsia. It is this form to which the neurasthenic and overworked, and also women with pelvic trouble, are especially prone.

Symptoms.—It must be admitted that the only constant feature of nervous dyspepsia is the etiological one, yet we may find symptoms to aid a diagnosis apart from the cause. *Pyrosis*, accompanied by *loud, noisy eructations*, is quite characteristic, while *noisy rumbling of the bowels* is often heard, caused by hyperperistalsis. On the other hand, *vomiting* is rare. There is also often *palpation* of the heart, with other nervous symptoms. *Constipation* is sometimes present. The nervous dyspeptic is less disposed to be anxious about himself or to dwell on his ills than is he with catarrhal dyspepsia, but may also be restless and sleepless, and depressed in spirits. As in catarrhal dyspepsia there may be *loss of appetite*, an *unpleasant taste* in his mouth, *nausea*, *dizziness*, *headache*—pressure on the head. So, too, a *sense of discomfort* in contrast to sharp pain; also distention during digestion, but in nervous dyspepsia, if the interest of the patient is strongly excited by external matters, as, for example, pleasant society or even business interest, he may for the time forget it. *Gastralgia* may, however, be associated, especially the form attended by hyperacidity.

Wilhelm v. Leube, who has given the subject of nervous dyspepsia much attention, makes three clinical varieties:

1. Those in which the hydrochloric acid is present in normal amounts, which he says may be regarded as a fundamental type.
2. Those in which the HCl is diminished.
3. Those in which the HCl is in excess.

In each of these cases the digestion is complete at the end of the normal time, except that sometimes it may be delayed for starches in the third type of hyperacidity. Thus, while nervous dyspepsia is chiefly a sensory neurosis, it is to a less degree secretory and also, to a degree, motor, as evidenced by the occasionally associated hyperperistalsis.

An annoying symptom that is sometimes associated with nervous dyspepsia and is at times its chief manifestation is *peristaltic unrest*. *Borborygmi* and gurgling set up very soon after eating, so loud as to be heard at a distance, and thus to become often a mortification to the patient, while this very emotion reacts to increase it. The movement extends to the lower bowels. The associated discomfort varies greatly and is sometimes extreme. Peristalsis may be reversed, and in extreme cases it is said that enemas and even fecal matter have been discharged *per orem*.

Diagnosis.—The frequent dependence of nervous dyspepsia on other conditions requires a broad etiological study. Thus, as v. Leube suggests, we have first to settle the question as to whether it is an independent affection or a part of a neurasthenia. The urine should be studied, because the phenomena of nervous dyspepsia are sometimes a manifestation of uremic intoxication of a mild degree in contracted kidney. The spleen should also be explored, because the malady is sometimes a result of malaria. In still other cases it is a symptom of chlorosis or hysteria. In all these cases the nervous dyspepsia is the effect of the operation of the disease on the nervous system, and again in other cases it is the result of sympathy with sexual diseases, especially in women with disease of the uterus and ovaries.

Again, we have to distinguish it from *ulcer of the stomach*, which the hyperacid form resembles, but from which it differs in that the pain is relieved by pressure and sometimes by taking food, both of which acts increase the pain in ulcer. The occurrence of hemorrhage from the stomach, of course, under these circumstances points definitely to ulcer. Nervous dyspepsia may, however, continue as a sequel of both healed ulcer and gastric catarrh, since their effect is a neurasthenic one. Finally, it is to be distinguished from the form of *catarrhal dyspepsia* with similar symptoms by the delayed completion of the digestive act characteristic of the latter, as well as the etiological factor, which is the most important criterion.

Treatment.—The treatment of nervous dyspepsia varies with the cause, but it is desirable also to determine by chemical examination the state of secretion, whether normal, hyperacid, or of diminished acidity. The treatment of all three forms is, however, largely a moral one, since nervous influence may be at once a cause of increased or diminished HCl secretion, but this is especially true of the type attended with normal secretion. The patient must be assured that there is no organic disease and be compelled to desist from self-study. Along with this, his general muscular and nervous tone must be improved. He must be encouraged to take food and not to avoid it, and the moral effect of a systematic arrangement of diet is good. The neuro-tonics, strychnin, gentian, nux vomica, taken with meals are helpful, but too much medicine is harmful. Occasionally the nervous sedatives, including the bromids and valerian, are of service.

When there is scanty secretion of HCl this acid must be given according to the rules already laid down, 15 to 30 minims (1 to 2 gm.) of the dilute hydrochloric acid fifteen minutes to half an hour after a meal. On the other hand, if there is excessive HCl, alkalies must be prescribed as directed in the section on Hyperchlorhydria.

Atonic Dyspepsia—Simple Atony of the Stomach of Nervous Origin.—Atonic dyspepsia is a variety of nervous dyspepsia, especially common in neurasthenics, which scarcely deserves separate description; but as the term is frequently employed, some attempt should be made to direct its correct application. If used, it should be applied to cases in which delayed gastrointestinal activity or muscular atony, with *stasis of the gastric contents*, is the characteristic feature. As such it may be a variety of catarrhal dyspepsia or of dilated stomach. In such cases a considerable portion of a test-meal may be withdrawn at the end of seven hours. It is probably associated with more or less deficient secretory activity, though not always. Under these circumstances, too, there is apt to be flatulent distention of the abdomen, whence the terms *flatulent dyspepsia* and *intestinal dyspepsia*. A further natural consequence of such delayed mobility is *constipation*.

True gastric atony is also characterized by other symptoms which are not commonly included under those of atonic dyspepsia. Such condition undoubtedly plays a part in dilatation of the stomach, an important morbid state to be separately considered. Such atony, also, involving the cardiac orifice, favors eructation and regurgitation from the stomach, an extreme degree of which is the rare condition of rumination, or *merycismus*, in which the patient regurgitates the swallowed food, oftentimes voluntarily, and chews it again like ruminants. Such a power of regurgitation had the late Brown-Séquard. It is sometimes hereditary, and may be taught to others.

GASTRALGIA.

Definition.—A term applied to recurring attacks of gastric pain of great severity without discoverable organic lesion or deranged function.

Etiology.—The disease is confined almost exclusively to women, but does occur occasionally in stalwart men. It is more frequent in weak, anemic women, and those subject to menstrual derangement, in brunettes rather than in blondes. It is especially frequent and severe about the menopause, but does not cease with it. Excessive secretion of gastric juice, or hyperchlorhydria, is a cause of gastralgia, but the condition is one for separate consideration. It is usually independent of exciting cause, such as the taking of food, but it may be thus induced.

Symptoms.—The attack may come on suddenly or with gradually increasing severity first in the neighborhood of the ensiform cartilage, whence it radiates into the back and around the lower ribs. It is a *boring, burning pain* of extreme severity, sometimes causing fainting and collapse, relieved by pressure, such as is produced by boring the fist into the epigastrium or pressing it against some hard substance. On the other hand, it is sometimes excited by pressure. Its most striking feature, after its agonizing severity, is its *intermittent paroxysmal* character, whence it has been held to be malarial in origin. The pain is usually the sole symptom, but it may be associated with *nausea* and *vomiting* or with nervous symptoms, such as *globus hystericus* and *unnatural hunger*. The attack, after a variable duration of from a few minutes to an hour or more, may subside gradually or suddenly without other symptoms, though sometimes with vomiting and eructations, at others with the discharge of a large quantity of pale urine. One case under my care almost always began with a chill, more or less typical, and it is certain that there was no malaria. The interval between the attacks varies greatly. It may be a week or it may be months.

Diagnosis.—Essential gastralgia is to be differentiated from intercostal neuralgia and the so-called symptomatic gastralgia due to ulcer, rarely cancer, from the gastric crises of *tabes*, and from biliary and intestinal colic.

In *intercostal neuralgia* the pain is not so severe and the paroxysms are of longer duration, while careful examination will discover its focus in an intercostal situation as compared with an epigastric. In *ulcer of the stomach* there is not that total intermission or longer interval of total intermission characteristic of gastralgia, while the general health of the patient with ulcer is commonly more seriously affected. This is, however, not always so, as gastric ulcer may be associated with robustness of appearance. In gastric ulcer pressure increases the pain, while in gastralgia it tends to relieve it. *Carcinoma*, as contrasted with gastralgia, always visibly affects the general health. Careful examination will generally discover a different seat of the pain in *biliary colic*, while the almost invariable presence of jaundice settles the question. In a well-established case of *tabes* there need be no difficulty in diagnosis, but in cases where the diagnosis is not well established there may be much doubt. The history of attacks in comparatively early life and thence throughout life point to gastralgia. *Abdominal colic* has a different focus and is more apt to be associated with gaseous distention.

Prognosis.—True gastralgia never destroys life, but the attacks may continue to recur at intervals throughout it.

Treatment.—The severest attacks of gastralgia can only be relieved

by the use of *morphin*, which is best given hypodermically in the smallest doses which will suffice. Exceeding care must, however, be exercised to avoid a morphin habit. In milder cases chloroform may answer the purpose, or a combination long prescribed in the clinics of the University of Pennsylvania and deservedly popular is, equal parts of chloroform, compound tincture of cardamom, aromatic spirit of ammonia, and brandy, of which a teaspoonful may be given every half hour or fifteen minutes until relief occurs. If needed, a few drops of deodorized tincture of opium may be added to each dose to increase the anodyne effect.

Anemia should be treated with iron and arsenic, and a change of scene is often beneficial, while sea-bathing is a form of hygiene which is sometimes especially useful. The bowels should receive careful attention. If neurasthenia or hysteria be present, the rest cure, associated with massage, as described under the appropriate section, is often an efficient cure.

HYPERCHLORHYDRIA.

SYNONYMS.—*Nervous Hypersecretion of Hydrochloric Acid; Hyperpepsia.*

Definition.—Hyperchlorhydria, or an excess of hydrochloric acid in the gastric juice, is a symptom of different morbid conditions of the stomach, notably ulcer and nervous dyspepsia. In a certain number of cases, however, being the chief symptom and apparently independent of any stimulus like the presence of food, it may be studied as an independent neurosis. The term *hyperpepsia*, suggested by Hayem, is not correct, since this state is not characterized by excess of the digestive ferment, but of the chlorin element, especially hydrochloric acid. In normal digestion the total acidity as represented by free and combined HCl may be put down at 1.8 to 2 parts per 1000, while in hyperchlorhydria it may reach 3 and 4 parts in 1000.

Eliminating the hyperchlorhydria included under nervous dyspepsia and ulcer of the stomach, there remain two varieties:

1. Simple paroxysmal hyperchlorhydria, lasting for an hour or several days.
2. Continuous chronic hypersecretion, which takes place spontaneously during fasting, or, even though excited by food stimulus, continues after the latter has ceased to act. The latter variety is also called Reichmann's disease, after him who first described it.

Etiology.—Both forms of hyperchlorhydria are most frequent in neurasthenics and emotional persons, but occur also in connection with other neuropathies, such as migraine, chlorosis, and tabes. The simple form occurs also where there is ulcer of the stomach, and more rarely with cancer and gastritis.

Symptoms.—In *paroxysmal hyperchlorhydria* there are *pain* and *epigastric discomfort*, *eructations*, *heartburn*, *thirst*, *nausea*, and even *vomiting*, *headache*, and *constipation*. The attacks may last for an hour, or may extend over several days, terminating in vomiting; or by remedial measures, such as drinking large quantities of water, which dilutes the acids, or by saturation with albuminous food, with which it enters into combination. The *urine*, because of much ingestion of albuminous food, is apt to be highly charged with urea.

In the *continuous form* the same symptoms are present, but without

intermission. The pain is even more severe, and is especially prone to come on at night; there is a *capricious appetite*, which is often excessive. Where the appetite remains, pain may occur several hours after taking food. The *vomiting* is often copious, gaseous, may contain remnants of undigested starchy food, and is of *intensely acid* reaction. It is likely to take place several hours after a meal, also at night. The *urine is scanty* and there is *constipation*. The patients gradually emaciate and become anemic, even though they may take a good deal of food.

A very frequent consequence of continuous hyperchlorhydria is *dilatation of the stomach*, as originally pointed out by Riegel, the distinctive symptoms of which may ultimately be added. The dilatation may be caused by spasmodic contraction of the pylorus, due to the irritation of the hyperacid gastric juice, or to the accumulation of fluid and undigested food in connection with a *nervo-motor atony* of the muscular coat of the stomach. As the dilatation increases there may ensue atrophy of the glandular structure of the stomach, and while the hypersecretion persists the hyperchlorhydria gradually diminishes and may disappear. In such event there may be an excess of fixed chlorids in the gastric juice secreted by the mucous membrane, which is, however, incapable of elaborating hydrochloric acid. *Gastritis* is also a result of hyperchlorhydria and contributes further to the symptoms, especially to pain.

Diagnosis.—A positive diagnosis of hyperchlorhydria can only be made through analysis of the gastric contents. This is done in the sixth hour after a test dinner, with a view to discovering the presence of an excess of hydrochloric acid. The same symptoms may, indeed, be caused by organic acids, while the hydrochloric acid is in normal amount. If the stomach is washed out in the evening and the next morning, no food being ingested in the meantime, the contents are expressed and found to be hyperchlorhydric, the condition is one of continuous hyperchlorhydria. Microscopic examination of the gastric contents may also aid in the diagnosis. Such examinations made one to one and a half hours after a test breakfast or three to four hours after a test dinner, will often reveal a large number of unaltered starch-corpuscles, instead of only a few as in normal digestion, while the so-called snail-like cells are often found in this condition, as originally shown by Jaworski. They are also, however, found in patients with normal secretion.

Prognosis.—The prognosis of simple hyperchlorhydria is favorable; that of the continuous form is grave, the disease being incurable after a certain stage has been reached. It becomes, therefore, important to treat the simple form promptly and intelligently before it passes over into the continuous form.

Treatment.—The indications for treatment in hyperchlorhydria are evident. Their measure should, however, be based upon the estimation of the acidity of the gastric contents. They are (1) to neutralize the excessive acid secretion, and (2) to restrain its formation.

The first indication is met in two ways:

- (a) By saturating the acid by nitrogenous food.
- (b) By the administration of alkalis.

(a) The former is fulfilled by the use of *meat and milk diet*. It has, however, its limits, because when the tendency to acid secretion exists, it is often maintained even after that present is combined with any albuminous food that may be in the stomach. Hence it is that the pain is felt some hours

after a meal when the albumin is digested. (b) Since there is a limitation to the ingestion of meat its use must be supplemented by *antacids*, which further neutralize the effect of the acid. The alkali most frequently employed for this purpose is sodium bicarbonate, though calcined magnesia is in some respects better because of its greater saturating power. Prepared chalk was far more efficient than any other alkali in one case under my care. An idea of the amount of hydrochloric acid secreted may be obtained from the fact that probably a half liter (about a pint) of gastric juice is secreted in an hour, four or five liters (8.4 to 10.5 pints) in three hours, and should such gastric juice contain 3 parts of HCl in 1000, a proportion often exceeded in hyperchlorhydria, there would be some 12 to 15 gm. (180 to 225 grains) of the HCl to neutralize. Since 1 gm. of hydrochloric acid requires 1.48 gm. *sodium carbonate*, 20 to 25 gm. (300 to 375 grains) would be required to neutralize the whole amount of acid—a large quantity. The sodium carbonate should be administered some time after meals, just before the time the pains are expected. It should be dissolved in water or milk, or put in capsules or cachets. The doses should be sufficient to counteract the acidity—*i. e.*, 10 to 20 grains (0.66 to 1.3 gm.) or more. The quantity of carbonic acid evolved sometimes distends the stomach uncomfortably. Smaller doses of *calcined magnesia* suffice, and it is surprising that its use is not more general. It has the disadvantage of being insoluble in water, but not only are smaller doses sufficient, but there is also absence of carbonic acid evolution. It is indicated especially where there is constipation.

Other alkalis may be used, such as the potassium salts, and the official *liquor potassæ* in 15 to 30 drops (0.8 to 1.7 c. c.) in milk may be used with benefit. The *benzoate of sodium* may be prescribed in 10-grain (0.66 gm.) doses where antiseptis is required or fermentation is present. *Lime-water* is also useful, but large doses are required, as its neutralizing power is small. One-half ounce to an ounce (15 to 30 c. c.) or more should be given. Lime dissolves more largely in saccharine solution than in pure water, and larger doses may thus be given in smaller bulk. Dilute alkaline mineral waters, such as Vichy or Vals or Contrexville, may be used during a meal.

(2) Constitutional treatment should be directed to the cause, if it can be ascertained, neurosis by suitable remedies, chlorosis by iron and arsenic. Of course, it is better, if possible, to prevent the excessive secretion of the juice. For this purpose *sodium sulphate* has been recommended, more particularly in the shape of Carlsbad water. Or the sodium sulphate may be dissolved in Vichy, say 45 to 90 grains (3 to 6 gm.) in a glass. It is given in the morning before breakfast, or, if necessary, may be given before the other meals.

Diet.—While the medicinal treatment of hyperchlorhydria is in most cases indispensable, the diet is equally important. It has already been said that theoretically a meat and milk diet is indicated, because meat and milk consume in their digestion the excess of HCl. On the other hand, the starchy foods are but imperfectly digested. Imbibing the acid secretion, they swell up, but do not dissolve, while they favor, on the other hand, irritating acid fermentation. Others object to meat diet because of its overstimulating effect on the acid secretion, and recommend vegetables instead. This is, however, fallacious, and experience sustains the verdict in favor of meat and a minimum of starchy foods. It should be finely cut and well masticated, while meat powder may be substituted. Milk should be the drink,

though the alkaline mineral waters may be taken at meals. In extreme cases a pure meat diet, the meat raw or nearly so, finely minced and spread on bread, may be necessary. A meal may consist of about 3 1-2 ounces (100 gm.) of raw meat, a couple of thin slices of stale bread or Zwieback, a little butter, and a glass of plain water or weak alkaline water, such as Vals or Vichy. Or an exclusive milk diet may be tried, in which event the milk should be well alkalized or peptonized. To these are added, as the case improves, raw meat or meat powder or meat juice and eggs, and later still starchy foods may be tentatively given, associated with diastasic malt. Where acid secretions and undigested residue of food remain in the stomach long after the ingestion of food, the organ should be washed out. This may be done two or three times a week, or even daily.

In these cases overstimulation of the stomach, induced especially by alcohol, or by pepper, mustard, and other condiments, should be avoided. In like manner coarse food of any kind is contra-indicated in these cases. On this account constipation is sometimes best treated by enemas, in order to avoid the administration of irritating medicines by the stomach.

Of medicines other than those intended to meet the symptoms, arsenic, in the shape of Fowler's solution, is sometimes efficient. Long courses of it should be practiced, but large doses are not often allowable because of the irritation excited by them. Silver nitrate may also be employed in doses of 1-4 grain (0.0165 gm.), in which dose it is sometimes sedative when given on an empty stomach.

Anorexia Nervosa.—This term is applied to a condition in which absolute loss of appetite is the chief and characteristic symptom. Associated with this are, naturally, great debility, shortness of breath, dizziness, constipation, and sometimes headache; rarely, also, vomiting; sooner or later, emaciation. In women, in whom the symptoms usually occur, there is cessation of the catamenia. The name was suggested by Sir William Gull.

Prognosis.—This is favorable, cases being rarely, if ever, fatal.

Treatment.—The usual tonic measures are likely to fail to excite appetite in these cases, and nourishment must often be given either by the rectum or by forced feeding. The latter is done as follows: A short rubber tube, long enough to reach just below the cricoid cartilage, is introduced as directed on page 323. A bottle or funnel should be attached, and from this liquid nourishment is slowly introduced. This may be milk, plain or peptonized, broths or eggs, Murdoch's or Mellin's food. Estimating that 3 1-2 ounces (100 gm.) of albumin, 5 ounces (150 gm.) of fat, and 10 ounces (300 gm.) of carbohydrates are a sufficient amount per diem, Wiessner recommends 1 quart (1 liter) of milk, 2 ounces (60 gm.) of butter, 6 eggs, and 3 1-2 ounces (100 gm.) of sugar to be mixed and warmed while stirring. One-third of this amount is introduced three times daily. The food is usually easily digested, for it is not the digestion which is at fault, but the appetite, and the patient, encouraged by the result of forced feeding, is stimulated to eat for herself.

Nervous Vomiting.—A form of vomiting resulting from direct or reflex irritation of the centers presiding over vomiting, and independent of anatomical lesion in the stomach. Like nervous dyspepsia, it is probably an expression of a general irritable condition of the gastric nerves—a manifestation of a general neurasthenia. It has been suggested that the exciting cause is some irritating leukomatin of unknown nature.

Etiology.—Its subjects for the most part are hysterical and neurasthenic women, more often of dark complexion; but it is also the result of disease of the brain and its membranes and of the medulla and spinal cord, such as tabes dorsalis, when it may take the place of other symptoms of gastric crisis. It is apt to be associated with headache and gnawing sensations in the stomach, with diseases of the kidneys, liver, uterus, and other distant organs. While more usual in adults, it may also occur in children. Pure nervous vomiting is especially seen in neurotic families in which there is a tendency to nervous disease, including insanity and epilepsy. On the other hand, the absence of the hysterical temperament is often conspicuous. It affects rather the upper classes.

Symptoms.—Especially characteristic of nervous vomiting are the *absence of nausea*, the *suddenness* of the act of vomiting, and the absence of the straining. More rarely there is nausea. The *appetite* is good and the vomiting generally follows a meal, but it may also occur at irregular intervals. In the absence of organic nervous disease the patient may be well nourished. There may also be *constipation*, *headache*, *dizziness*, and *epigastric pulsation*. Intense *acidity of the vomited matter* may be present. To this condition Rosenbach has applied the term *nervous gastroxynsis*. In one of his cases the HCl reached four per cent. In the typical form, however, the vomitus is not abnormally acid, and in this respect it differs from acid dyspepsia and Reichmann's disease. The duration of the vomiting varies. It may be a single act or it may last for twenty-four hours.

Diagnosis.—This is based, in the first place, on the exclusion of those organic diseases of the stomach which cause vomiting, and, in the second place, on the presence of any one of the affections named as possible causes.

Prognosis.—Except when associated with organic nervous disease, this is ultimately favorable. George M. Garland* reported a fatal case of apparently pure nervous vomiting. At autopsy the mucous membrane of the stomach was found thin, and reddened on its inner surface with minute hemorrhagic points. There was slight interstitial nephritis too insignificant to have had any effect, and the gastric changes were probably secondary, so that the case may be regarded as purely neurotic.

Treatment.—When vomiting is the result of organic nervous disease, the fundamental treatment must be that of the disease itself. Temporary relief may be afforded such cases by measures which make a profound nervous impression. Such, pre-eminently, is the *blister* to the epigastrium. The suddenness and irregularity of the vomiting make it almost impossible to provide against a given event. So that *ice*, internal or external, *sinapisms*, *dry cupping*, and similar measures efficient in continuous vomiting or in vomiting preceded by nausea are scarcely available. When, however, circumstances permit their employment, they should be used.

Nerve sedatives, including the bromids and valerian, may be used, but hypodermic injections of *morphin* are often necessary, and are usually very efficient. When practiced by the physician only, they become a safe measure. *Rectal alimentation* should be employed when the vomiting is obstinate, and has apparently saved life in many instances. When there is nervous gastroxynsis, lavage with warm water may be used with advantage, as recommended by Rosenbach. The headache, etc., apt to be associated with this form is at once relieved.

* Garland, G. M., "Trans. of the Assoc. of Am. Physicians," vol. iv., 1889.

GASTRIC AND DUODENAL ULCERS.

SYNONYMS.—*Ulcus ventriculi pepticum*; *Peptic Ulcer*; *Simple or Round Ulcer*.

Etiology.—There is probably more than one mode of origin of gastric ulcer. It may have its origin in *mechanical injury* associated with *feeble nutrition*, which permits the gastric juice to digest out the mucous membrane to various depths, resulting in the formation of an ulcer. Such mechanical injury may be due to pressure exerted in the course of one's occupation, such as shoemaking, washing, tailoring, and the like, in which pursuits the costal cartilages are pressed against the stomach. The second of these conditions—for it is likely that neither would be alone sufficient to produce the lesion—is produced by such states as *anemia*, *chlorosis*, *heart disease*, *Bright's disease*, and the like. *Overdistention* of the stomach, it is claimed, may be a predisposing cause by interfering with its proper nutrition and thus favoring the action of the gastric juice.

Thrombosis and *embolism* have been held responsible for a certain number of cases of ulcer since Virchow called attention to such causes. Embolism of the gastric blood-vessels is extremely rare, but thrombosis is a not infrequent result of obstinate vomiting, as is also punctiform hemorrhage. The stasis of circulation thus resulting affords favorable foci for the solvent action of the gastric juice, and certainly no theory explains so satisfactorily the crater shape of many gastric ulcers. Böttcher ascribes ulcer of the stomach to *micrococci*, numbers of which have been found by him in the margins of gastric ulcers. The well-known clinical fact that the gastric juice in ulcer of the stomach exhibits intense acidity, while traumatic ulcers of the stomach produced under ordinary circumstances tend to heal promptly, has led to the suggestion that undue *acidity* plays an important rôle in the causation of ulcer. The same causes operate to produce the duodenal ulcer.

The statements of authors as to the frequency of ulcer of the stomach vary greatly. Thus, Ewald says 5 per cent. of Germans have ulcer. Truly, the disease is not nearly so common in America. Yet the discovery at autopsies of unexpected ulceration goes to show that it may be more frequent than is supposed. Women are much more frequent victims than men. While both the very young and the very old are commonly exempt, the period being between seventeen and twenty-five, gastric ulcer has been found in infants and in adults as old as sixty. In women gastric ulcer usually occurs between the ages of twenty and thirty; in men, between thirty and forty.

Duodenal ulcer, on the other hand, is more common in males, in the proportion of 178 to 41, in the combined statistics of Kraus, Chvostek, Lebert, Trier, and William Osler. The last-named observer found it once in a boy of twelve. Its association with extensive *superficial burns* and *tuberculosis* should be mentioned. It is commonly situated within 1-2 inches of the pylorus, though Schwartz reports a case where perforation was found on a level with or a little below the ampulla of Vater, permitting a free escape of bile into the peritoneal cavity.* This condition is much more apt to be confounded with other surgical lesions of the abdomen, and especially appendicitis.

* Quoted by Robert F. Weir in an admirable paper on "Perforating Duodenal Ulcers," in "The Medical News," May 5, 1900, p. 690.

Morbid Anatomy.—Gastric ulcer must be distinguished from post-mortem softening or digestion, which is found after death in stomachs in which gastric juice happens to be present at the moment of death. In this there may be erosion of the superficial mucosa, but nothing comparable to ulcer. The seat of postmortem softening is more commonly the fundus and posterior surface, where the gastric juice naturally collects.

The typical gastric ulcer is circular in outline, often with sloping, clean-cut sides, furnishing a crater or truncated cone shape, with the broad end superficially placed, corresponding to that of an infarcted area due to embolism or thrombosis. The term "punched out" has long been applied to characterize the appearance of a gastric ulcer. The sides are not always, however, smooth, being sometimes uneven or "terraced." Very rarely ulcer may be multiple. It is far more frequent on the posterior wall of the stomach near the lesser curvature. W. H. Welch's extensive studies of hospital records furnish the total of 783 cases, of which 288 were in the lesser curvature, 225 on the posterior wall, 95 at the pylorus, 69 on the anterior wall, 50 at the cardia, 29 at the fundus, and 27 in the greater curvature. The lesser curvature and posterior wall are, therefore, the more frequent seats. This is the result also of Langerhans' studies, though Ewald and Nolte, from a very much smaller number of cases, conclude that more ulcers are found at the greater curvature and pylorus. The duodenal ulcer is found just outside the pylorus, but may occur as low down as the biliary papule. It presents the same appearance as the characteristic gastric ulcer.

The floor of the ulcer is usually the muscular coat, but it may be the serous coat, which is sometimes perforated so that the floor may be formed by an adjacent organ to which the stomach has been glued by adhesive inflammation. The ulcer is usually small, not larger than a pea, but it may be 10 or even 15 cm. (4 to 6 inches) in diameter, covering the whole lesser curvature and part of the anterior and posterior walls. Ulcers may heal, leaving a cicatrix, which, if large, causes contraction and deformity, distorting the organ even to an hour-glass shape and producing stenosis of the pylorus. It is not unusual to find healed ulcers at autopsies. Or *the ulcer may perforate*, causing fatal peritonitis when in the anterior wall; or, if apposed to neighboring organs, these may be burrowed into. Thus the pericardium and left ventricle, the spleen, the head of the pancreas, the left lobe of the liver, the gall-bladder, the omental tissues, the pleura, and even the lungs have been invaded, while fistulous communications have been formed with the duodenum, the colon, and even the external air in the neighborhood of the umbilicus. Perforation of the posterior wall opens the lesser peritoneal cavity, and may perforate the pleura, producing subphrenic pyopneumothorax.

It is not unusual to see at the bottom of an ulcer an eroded blood-vessel from which there has been a fatal hemorrhage. The vessels invaded may be the gastric artery of the lesser curvature, or the splenic artery in the posterior wall; or, in the case of a duodenal ulcer, the pancreatico-duodenal artery; or it may be the hepatic artery, and even the portal vein. Small aneurysms have been found in the floor of an ulcer.

Gastric ulcer may be multiple, it is said, as often as once in every five cases. Osler records a case in which there were 5 ulcers and refers to a case, reported by Berthold, in which there were 34.

Symptoms.—The most prominent symptoms of ulcer of the stomach are *pain, tenderness, vomiting, hemorrhage*, and sometimes a tumor, but none of these is invariably present. They require to be separately considered.

Pain, with tenderness, is the most constant symptom. It is characteristic of the pain of ulcer of the stomach that it occurs almost immediately after taking food, especially after cold or hot and indigestible food; but it may also occur in an empty stomach—that is, several hours after a meal, when all food has disappeared. The latter pain is, however, of a different kind, being of a gnawing character, and is even temporarily relieved by taking food. The pain typical of ulcer—a gastralgia, coming on in from ten minutes to half an hour after eating—is perhaps due not so much to the presence of the food as to the irritant effect of the acid gastric juice called out to digest it. It varies greatly in severity, and is further characterized by having a definite center of greatest intensity, commonly in the epigastrium near the xiphoid, less often at a point behind the shoulders, from which it radiates in all directions. A change of position also sometimes increases it, especially turning to the right side, probably due to the irritation of the ulcer by the moving gastric contents. The paroxysms are sometimes of indescribable severity, requiring the hypodermic use of morphin to relieve them, though they may also be relieved at times by a full dose of sodium bicarbonate, the effect of which also explains their immediate causation. Commonly increased by pressure, it is sometimes relieved by it, and the patient will bend over, pressing his fist into the epigastrium or leaning over the back of a chair to secure relief.

Tenderness on pressure is a characteristic symptom, apart from the paroxysms of pain; and in order to guard against it, the patient may wear the waistband low. Boas has devised an instrument by which circumscribed pressure may be conveniently induced and diagnosis facilitated. It is, however, necessary to exercise care in such pressure, as perforation may be produced. The *tender point is more frequently an inch or two above the umbilicus*. In cases of ulcer of long standing palpation may recognize a *tumor*, the result of inflammatory thickening in the vicinity, and I well remember a case where, in consequence of the distinctness of the tumor, I diagnosed with some confidence a cancer of the pylorus, and a few days later the patient died of a hemorrhage from the stomach. An autopsy revealed extraordinary thickening of the pylorus, penetrated to a great depth by an ulcer, at the bottom of which lay a little perforated artery, whence came the fatal hemorrhage.

Vomiting is not so frequent a symptom. When present, it occurs usually soon after the ingestion of food, about the same time as the pain. It often includes acrid acid matters.

And this brings us to *hemorrhage*—hematemesis—a most valuable sign of gastric ulcer. Given a copious hemorrhage of pure red blood from the stomach, with the symptoms described, or even no other symptoms, it can scarcely be due to any other cause; since although cancer gives rise to hemorrhage, the blood is mixed with mucus; it is usually less copious, while a cancer with hemorrhage rarely fails to furnish also the other symptoms of cancer. In a few instances in ulcer the hemorrhage is small, when, of course, the diagnosis becomes more difficult. When the hemorrhage is large, blood quite black is found also in the stools. Indeed, sometimes the presence of blood in the stools is the first intimation of gastric hemorrhage. Especially is this the case when the ulcer is duodenal. A very remarkable case of this kind came under my care in a nurse at the Philadelphia Hospital. When I first saw her, her appearance and condition suggested hemorrhage from somewhere. She was extremely weak, and her lips were bloodless. Her

skin was as white as marble. Yet no sign of hemorrhage appeared at the time of examination. Three hours later she had a copious hemorrhage from the stomach, and further examination elicited the fact that *her stools had contained blood for two days*. Hemorrhages from ulcer are also often recurrent, and result at times in intense anemia of the subject. They are not rarely fatal, more frequently syncopal, bringing their subjects to the verge of the grave, from which there are often also surprising recoveries. A hematemesis of 10 pounds (4 1-2 kilos) is said to have been followed by recovery. Vicarious hemorrhage in menstruating women is to be remembered as a possible event, but the hemorrhage is not usually copious, and its association with amenorrhea aids in clearing up doubt. Hemorrhage occurs in more than half the cases, at least in hospital practice, since the severest cases come to hospitals. In private practice the proportion is smaller.

In this place it may be appropriate to mention what has been called *parenchymatous* hemorrhage, in which there has been fatal hematemesis in which no ulcer has been found at necropsy. It is more than likely that some of these cases may have been cases in which the ulcer eluded examination, but others are too well authenticated to be thus explained.

Perforation is a rare accident in ulcer of the stomach. It is variously stated at from 6 to 18 per cent. of all cases. Its characteristic symptoms are sudden and violent pain, extreme tenderness, rigid contraction of the abdominal muscles, profound shock, shallow breathing, and absence of the normal hepatic dullness—in a word, the symptoms of peritonitis, followed by those of shock. Perforation is much more frequent when the ulcer is in the anterior wall. Thus, in 13 cases reported by A. B. Mitchell to the "British Medical Journal," March 10, 1890, all were in the anterior wall.

The milder *symptoms of dyspepsia* may also be present in various degrees, including a sense of *fullness in the epigastrium, acid eructations, heartburn, and loss of appetite*.

Patients with gastric ulcer lose in weight and become gradually *anemic*, quite independent of hemorrhage, as evidenced by a blood count, which sometimes finds the red corpuscles less than a million to the cubic millimeter. This is probably due to the fact that they are afraid to eat enough because of the pain food gives them when taken into the stomach. This anemia is even a characteristic symptom, and should at once suggest a close examination as to a possible cause in ulcer.

Chemical examination of the stomach-contents after a test meal almost invariably shows an increase of HCl. Exception sometimes occurs when chronic catarrhal gastritis is associated.

Finally, it is to be remembered of gastric ulcer that it is often *latent* throughout, quite without symptoms during life, and recognized for the first time at necropsy, when, also, as already stated, healed ulcers are sometimes found.

Course and Termination.—The course of ulcer is usually slow, sometimes very protracted. One case, which had lasted twenty years, confirmed by autopsy, came under my treatment. A few cases are acute and rapidly fatal. The symptoms of gastric ulcer quite frequently disappear, and after a time, even considerable time, recur giving rise to the so-called recurrent forms.

Diagnosis.—In some cases this is easy; in others, difficult or impossible. If hemorrhage of the kind described is present in connection with the other symptoms named, it affords conclusive evidence of ulcer, but in its absence

there must often remain doubt. Aside from hemorrhage the most characteristic symptom is pain, and only in gastralgia and *tabes dorsalis* do such pains occur.

In *gastralgia*, as in ulcer, hydrochloric acid is increased, and the question often becomes a most difficult one to settle. In gastralgia, however, the general health of the patient is less severely affected, there is less chlorosis or menstrual derangement, and the pain has a less definite relation to taking food,—indeed, is often relieved by food,—while in ulcer the symptoms of dyspepsia are more constant. There are longer intervals between the attacks in gastralgia. Above all, in ulcer there is tenderness on pressure between the attacks of pain, a symptom absent from gastralgia, while pressure always relieves the pain of the latter. Indeed, in gastralgia dyspeptic symptoms between the attacks are generally absent. If palpation recognizes a hardening, there is further reason to believe the case is one of ulcer. We may look for assistance from the standpoint of etiology. Given the causes of ulcer, especially valvular heart disease with possible embolism, the vomiting which produces thrombosis, or the occupations which favor gastric ulcer, their import should be recognized. Gastralgia occurs in neurotic individuals—those subject to hysteria and uterine disease. Von Leube has called attention to an electrical test between gastralgia and ulcer—viz., if during digestion an electrical current, especially with the anode as a testing-pole, be applied, and the pain disappears completely, it is indicative of gastralgia; if, however, it does not cease, it may be either gastralgia or ulcer. Only the positive effect, the sudden cessation of pain on the application of the current, is of diagnostic value.

In *tabes* the gastric crises are almost identical with the severe gastralgic attacks of ulcer. But in *tabes* the appearance of good health is preserved, while it is not long before the distinctive symptoms of the disease show themselves, if they are not already present—viz., lightning pains, ocular symptoms, and absence of knee-jerks. In *tabes* the extreme acidity of the gastric contents characteristic of ulcer is wanting in most instances.

In rare cases *intercostal neuritis* may be mistaken for ulcer, if there be pain in the epigastrium associated with accidental dyspeptic symptoms. But in this affection painful points will also be found in the course of the intercostal nerves, while, if a large fold of the abdominal wall be raised, tender points will be found in it.

From *cancer* of the stomach ulcer sometimes is distinguished with difficulty in the absence of the more distinctive symptoms of the former disease. Heretofore much reliance has been placed on the absence or extreme diminution of free hydrochloric acid in cancer as contrasted with its excess in ulcer. It has, however, been realized also that it occasionally happens that the association of chronic catarrhal gastritis with ulcer may work reduction of HCl. The recent researches of Boas have, if confirmed, added a very much more reliable diagnostic sign in the invariable presence of lactic acid in cancer and its constant absence in ulcer, and, indeed, under all circumstances in which it has not been introduced from without. Other facts to be weighed in the balance as to the existence of cancer are a palpable tumor, the greater age of the patient (always over thirty), the extreme emaciation and cachectic appearance, and the intermittent vomiting of large quantities of accumulated ingesta, sometimes of blood mixed with mucus, or blood presenting the "coffee-grounds" character as contrasted with the bright clear blood of ulcer.

Rarely is *duodenal* ulcer distinguished before death from gastric ulcer,

though Burwinkel claims that by a careful study of the symptoms he has been able to diagnose five cases of duodenal ulcer in the last five years. The former may be suspected when pain is in the right hypochondriac region two or four hours after eating; also, if the blood be discharged by the bowel rather than vomited. Vomiting is less frequent than in gastric ulcer, and does not afford relief, as in the former. Jaundice is more frequent in duodenal ulcer. Jaundice is, however, more constantly, though not invariably, associated with biliary colic, which has also been mistaken for ulcer. In biliary colic the liver may be enlarged and tender and the gall-bladder distended, while the vomiting, which attends it as well as ulcer, is much less acid in reaction.

Attempts to locate the ulcer still more precisely have generally proved fruitless. Even when a single painful, unchanging, circumscribed spot has been noted, the apparent seat so rarely coincides with the actual seat that little encouragement is afforded further attempt. When pain immediately succeeds deglutition, especially of solids and hot and cold liquids, there is some reason to believe that the ulcer is in the neighborhood of the cardia, but it is by no means conclusive.

Prognosis.—Not only the disappearance of symptoms, but also the discovery of numerous healed ulcers at autopsies of patients dying from other causes, attest the fact that recoveries are not infrequent. Death is caused, as a rule, by hemorrhage or perforation, the latter followed by fatal peritonitis. At least six per cent. of all cases terminate in perforation, which, previous to the institution of operative treatment, was followed by death in the vast majority of cases, in a few hours. The proportion of death in all cases is estimated by W. H. Welch and A. B. Mitchell at 15 per cent.;* by Heydenreich at from 25 to 30 per cent.;† by v. Leube at 10 per cent.

Treatment.—The indications for treatment are evident, and are, in the main, easily fulfilled. It is plain, in the first place, that *food* which taxes the secretory or motor functions of the stomach is harmful, and that recovery will be still more likely to occur if the stomach can be placed at total rest, a condition easily met by rectal alimentation. It is clear, too, that absolute rest of body further fulfills such conditions. The greater the stringency with which these measures can be carried out, the greater the chances of a cure, which is always possible. It goes without saying that all solid food should be disallowed. The typical nourishment in my experience is peptonized milk, which should be given at stated intervals, the quantity adapted to the urgency of the symptoms, say 2 ounces (60 c. c.) every two hours, though even this amount may have to be reduced in serious cases, to be increased as danger subsides and the appetite of the patient demands it. Beef peptonoids and egg-albumen may be substituted for milk, or they may be conjoined with it.

So, too, when extreme danger of repeated hemorrhages is present, it is a warning that rectal alimentation alone should be relied upon; for which purpose, too, peptonized milk is also the best nutrient. Great care must be exercised in the use of enemas not to exhaust the toleration of the bowel. To this end they should be given at first tentatively and never oftener than once in eight hours, and should not at first, at least, exceed four ounces. This quantity, if borne, may be increased to six ounces. The various meat peptones, bouillon, or beef-juice may be substituted for or alternated with the

* "British Med. Jour.," March 10, 1900, p. 560.

† *Ibid.*, p. 564; quoted by Mayo-Robson from "Semaine Medicale," February 2, 1898.

peptonized milk, or an egg may be beaten up with the milk, though such addition is not often necessary. A nutrient injection which has given great satisfaction at the Hospital of the University of Pennsylvania consists of four ounces of milk (130 c. c.), to which are added two eggs, a pinch of salt and three drops of laudanum, the whole being predigested with pancreatin. The enema should be given through a long rectal tube, the patient having the hips elevated and the position maintained for an hour after the injection. In this way patients may be nourished for weeks with peptonized food, but it is rarely necessary to continue the rectal alimentation for more than a week or ten days. As the hemorrhage and vomiting cease the stomach may be tested, first with small amounts of peptonoids, gradually increased; and for a time the two methods may be pursued jointly, feeding by the mouth being increased, while that by the rectum is gradually withdrawn. Plain milk and beef-juice may be substituted for peptonized milk, and various thin gruels made with flour may be used as a change is demanded.

Lavage, which is of such signal service in chronic gastric catarrh, is hardly safe in ulcer on account of the danger of producing perforation; but in some cases, when vomiting has been obstinate, lavage has been found beneficial. To arrest the vomiting, it is safer to rely on rectal alimentation, though the usual remedies may be tried, including blisters to the epigastrium.

Medicines are not to be decried in ulcer of the stomach. Silver nitrate maintains the reputation it has so long enjoyed in the treatment of gastric ulcer. One quarter of a grain (0.016 gm.) three times a day or 1-6 of a grain (0.011 gm.) four times are the usual doses, given on an empty stomach. Of late I have been giving it by preference in solution in about 2 ounces (60 c. c.) of water. If there is pain, the extract of opium should be combined in pill in the same or larger doses, but should be dispensed with as soon as not needed. The extract of belladonna in small doses may be substituted as the opium is withdrawn. Its anodyne effect is perhaps slight, but it has a good effect upon the bowels. Local measures may be employed to relieve the pain, such as warm poultices and other hot fomentations to the epigastrium; and when more potent measures are needed, morphin may be used hypodermically.

The hemorrhage requires also to be met by remedies. For the present all astringent remedies have given place to suprarenal extract or its active principle adrenalin, of which 5 drops of a solution 1 to 1000 are a dose repeated. Gelatin is a modern remedy of which the value is exaggerated. It may, however, be used, especially as it serves also the purposes of a food. Two to three ounces may be given every six hours. Among the older remedies tannic acid is one of the best—in 15-grain (1 gm.) doses, every fifteen minutes, until the bleeding ceases. In the absence of this drug alum may be given, dissolving a teaspoonful in a glass of water, of which one-fourth should be given at short intervals. Pieces of ice may also be swallowed. After the attack is controlled the persulphate of iron, in doses of 1-4 to 1-2 grain (0.0165 to 0.033 gm.), in a pill three or four times a day, may be used to prevent recurrence. Recently Tripier has called attention to copious enemas of hot water for gastric hemorrhage, repeated twice daily, at a temperature of 112° to 120° F. (44.4° to 48.8° C.), conjointly with small doses of hot water by the stomach.

The acidity which is characteristic of the secretion in gastric ulcer has sometimes to be met, and for this purpose full doses of sodium carbonate or bismuth subnitrate, 15 to 30 grains (1 to 2 gm.), may be given. When

aperients are needed, as is sometimes the case, the Carlsbad salt becomes suitable, because of its alkalinity and its adaptation to the catarrhal state often associated with ulcer. A teaspoonful may be given in the morning dissolved in a glass of warm water, or a tablespoonful may be added to a pint of warm water and taken in divided portions during the day. Small doses of magnesium sulphate may be substituted, though, as a rule, the bowels should be regulated by enemata rather than by purgatives.

The resulting chlorosis or anemia may be treated with iron and arsenic. Of the former, the neutral preparations are to be preferred; of the latter, Fowler's solution, because of the easy regulation of the dose. Large doses of iron should not be given, since the excess of such doses remains unabsorbed, astringing and irritating the alimentary canal. The tincture of the chlorid, so valuable usually, is especially contra-indicated, because it increases the acidity of the gastric juice and thus favors the solution of the gastric wall.

Operative Treatment of Gastric Ulcer.—This has become an important measure of curative treatment, not only after perforation, but also for the cure of non-perforating ulcer causing recurrent hemorrhage. Operation for non-perforating gastric ulcer is recommended by modern surgeons in serious cases, and cases are considered serious where there is either very copious single hemorrhage or recurring hemorrhage. Thus, Dieulafoy advises operation after the first hemorrhage if as much as half a liter (500 c. c.) of blood is lost and if the bleeding is repeated in twenty-four hours. W. L. Rodman* says that "as soon as the bleeding from a second serious hemorrhage ceases and the patient has rallied from the shock and is in good condition," some operation should be performed. Rodman tabulates 63 operations for acute and chronic hemorrhage with 20 deaths, or a mortality of 32.6 per cent.

It is scarcely possible for recovery to take place after perforation without operation, but after operation at the present day at least 50 per cent. recover. The first successful operation was by Kriege, in Germany, in 1892. Up to 1894 results were far from satisfactory, when, of 85 cases collected by Mikulicz, only one recovered. On the other hand, out of 125 cases collected by Goffe up to the end of 1897, 63, or 50 per cent., recovered. Hence, operation should be borne in mind as a treatment for which we should always be in readiness.†

CANCER OF THE STOMACH.

SYNONYMS.—*Carcinoma ventriculi*; *Gastric Cancer*.

Etiology.—Little definite is known of the etiology of cancer. Heredity is an acknowledged factor, though it is less potent than is commonly supposed. W. H. Welch‡ was able to trace cancer, or at least a family history of cancer, in 242 out of 1744 cases. There is some evidence to show that abuse of the stomach by eating and drinking may be influential in causing the disease, though it is not conclusive. The same has been claimed for the depressing emotions. There is better reason to believe that ulcer is a predisposing cause, since autopsies have disclosed cancer developing in the floor of

* Oration on Surgery delivered at the Fifty-first Annual Meeting of the American Medical Association, Atlantic City, June 3-8, 1900.

† See also Dr. Weir's article, referred to, on "Perforating Duodenal Ulcers," "Medical News," May 5, 1900.

‡ "System of Medicine by American Authors," vol. ii. Philadelphia, 1886.

ulcers and in cicatrices. Mention should be made of the fact that a parasitic origin of cancer is claimed by some, but the subject is altogether too unsettled to justify more than reference in a text-book.

Gastric cancer is a disease of mature life, three-fourths of all cases occurring between the fortieth and seventieth year. One of my patients was thirty-two when he first consulted me, and died just one year later. Adolf Struempell has seen cases between twenty-two and twenty-five. George Dock * reports three cases occurring in his own practice, where the patients were twenty, twenty-four, and twenty-one years of age, confirmed by autopsy, and Marc Mathieu published in 1884 a monograph, "Du cancer précocose de l'estomac." The disease is slightly more frequent in men than in women.

Pathology and Morbid Anatomy.—After the uterus, the stomach is the organ most frequently attacked by cancer, a little more than one-fifth of all cases of *primary* cancer being found in this organ—according to Welch, 21.4 per cent., from an analysis of the very large number of 30,000 cases. It is far more common in the pyloric end and on the lesser curvature, 1300 cases collected by Welch being distributed as follows: pyloric region, 791; lesser curvature, 148; cardia, 104; posterior wall, 68; whole or greater part of the stomach, 61; multiple, 45; greater curvature, 34; anterior wall, 30; fundus, 19. Every variety of cancer is found in the stomach, in the following order of frequency:

1. Cylinder-celled epithelioma, most frequent at the pylorus.
2. Medullary or soft cancer, most frequent in the smaller curvature.
3. Scirrhus, at the pylorus and in the smaller curvature, causing, especially, stenosis of the pyloric orifice.
4. Colloid, diffuse infiltration with a tendency to spread to the peritoneum and adjacent organs.
5. Melanotic.
6. Squamous epithelioma, near the cardia.

All the forms start from the gland cells of the mucous membrane.

The medullary variety is prone to ulcerate and to form extensive fungoid ulcerated surfaces, from which there may or may not be hemorrhage. It may be associated with scirrhus. While nodular outgrowths are usual, the cancerous tissue may infiltrate the walls, producing diffuse thickening.

Secondary cancer of the stomach is an occasional event: in 17 out of 37 cases, according to Welch, secondary to primary cancer of the breast. I have met one case succeeding epithelioma of the lip. Much more frequently primary cancer of the stomach is a cause of secondary cancer elsewhere, most often in the adjacent lymphatic glands, which were the secondary foci in 551 out of 1574 cases collected by Welch; the liver was involved secondarily 475 times; the peritoneum, omentum, and intestine, 357; pancreas, 122; pleura and lung, 98; spleen, 26; brain and meninges, 9; other localities, 92; among the latter is to be included adjacent integument, especially about the navel.

Marked changes in the size, shape, and position of the organ occur as a result. Most common is dilatation, sometimes due to pyloric obstruction. Medullary cancer, on the other hand, is apt to produce a reduction in the size of the stomach and its cavity. A reduction in size may attend obstruction at the cardiac orifice, because of disuse of the organ, while the esophagus

* "Transactions of the Association of American Physicians," vol. xii., 1897.

itself may be dilated. The same effect may be produced by cancerous infiltration of the stomach walls, by which the capacity of the organ is greatly reduced—in one instance, a case of Livingstone's, to 12 ounces. Further reference may be made to extraordinary dislocation of parts of the organ in treating of symptoms. Adhesions may also form between the stomach and adjacent organs, and between it and the anterior abdominal wall. Peritonitis may occur; also perforation into an adjacent organ, as the transverse colon, and even the small intestine.

Symptoms.—The initial symptoms in almost every form of cancer of the stomach are those of indigestion, including *anorexia*, *eructations*, *vomiting*, *constipation*, *discomfort*, and *pain*, more rarely *acidity*. These are present for a variable time before a more serious condition is suspected. Increase in the severity of symptoms despite the use of remedies, progressive *debility*, *emaciation*, and *cachexia* invite closer examination, which may or may not result in the discovery of a *tumor*. Before a tumor is recognized there is often tenderness, which follows sooner or later, if it does not precede tumor. Cachexia and wasting may also be present a long time before the tumor is discovered.

A *chemical examination* of the *gastric contents* after a test meal may disclose the absence of free and combined hydrochloric acid or a minimum of it, and Boas' results are confirmatory of the persistent presence of lactic acid in decided quantity, to which, as well as to the absence of hydrochloric acid, attention was originally called by von der Velden. As to hydrochloric acid, it must be remembered that it is also diminished in gastric catarrh, in atrophy of the mucous membrane, in amyloid degeneration, and even in nervous dyspepsia at times, while in rare instances it happens that hydrochloric acid is increased in cancer. The motor as well as the secretory and absorbing functions will be found impaired, undigested food being found long after the seven hours' limit. Such motor delay characterizes more particularly the pyloric situation of cancer, with its resulting obstruction.

The Oppler-Boas bacillus was first described by Oppler in 1895, as an unusually long and thread-like bacillus, non-motile, found in the contents of carcinomatous stomachs.* The bacilli lie either end to end, in long thread-like chains, or at right angles to one another. They stain readily with anilin dyes. They prefer a medium containing lactic acid; indeed, Kauffmann ascribes to the bacillus the power of forming lactic acid from various kinds of sugar. Hydrochloric acid in any large proportion causes it to disappear. Schlesinger and Kauffmann declare the presence of large numbers of the bacilli in association with pyloric stenosis to be an indication of carcinoma, and their absence, associated with the absence of lactic acid, to be evidence against carcinoma. Riegel does not consider the organism pathognomonic of carcinoma, but very important in its diagnosis. Stockton says it is often present in carcinoma, and has not been found in other diseases of the stomach. The Oppler-Boas bacillus and sarcinæ do not coexist for any length of time in carcinomatous stomachs. The sarcina thrives in the presence of hydrochloric acid, and disappears with it, being replaced by the Oppler-Boas bacillus and lactic acid. Even when introduced into the stomach in cases of obstruction due to carcinoma, the sarcinæ disappeared in twenty-four hours, the Oppler-Boas bacillus seeming to replace them.

* Boas, "Specielle Diagnostik und Therapie der Magenkrankheiten." Oppler, "Deutsche medicinische Wochenschrift," 1895, No. 5.

In evidence of the value of the Oppler-Boas bacillus in diagnosis of gastric carcinoma it may be said that Kauffmann * found it in 19 out of 20 cases, and in the one in which it was absent there was no lactic acid. John C. Hemmeter informs me that he found the bacillus in 52 out of 55 cases, that he regards it "an important diagnostic sign in carcinoma of the stomach, within limitations, and though it is by no means pathognomonic." He has found it in a case of benign pyloric stenosis, and also in such cases when HCl was still present. Ullman, of Buffalo, N. Y., found it in all of 10 cases.

If this test should prove reliable at an early stage of the disease, the chances of success of operative treatment will be greatly enhanced.

Fig. 30.—Oppler-Boas Bacillus, from Contents of a Carcinomatous Stomach—
(Hemmeter).

At a later stage periodic vomiting of large quantities of fluid containing the ingesta of hours and even days previous is a characteristic symptom, and a dilated stomach may now be easily demonstrated. The vomitus may also contain blood, and that peculiar mixture of blood and gastric juice which is called "coffee-grounds" vomit. If, owing to their disintegration, the microscope does not recognize blood discs, Teichmann's hemin crystals may be easily prepared as directed on page 79, footnote. The vomited matter is sometimes very foul-smelling, as are also at times the eructations. Vomiting is by no means an invariable symptom, though even when there is no vomiting, nausea is commonly present. The absence of vomiting generally means that the cancer is not at the pylorus. It may be at the middle belt, at the fundus, or at the cardiac end. When at the latter point, there is almost always difficult and painful deglutition.

By this time the patient is emaciated, anemic, *cachectic*, with a peculiar yellowish, sallow, swollen appearance, and now a tumor is commonly easily recognized by palpation. Very interesting is the varying situation of the tumor, as well as at times its great mobility. Almost never, in my experience, is the tumor of pyloric cancer found in the normal situation of the pylorus, even when the patient is lying on his back, but rather in the neighborhood of the umbilicus, a little to the right or left. It is the weight of the tumor which drags it out of the normal position of the pylorus, and it may be found even lower down, toward the symphysis pubis, as in a case

* Kauffmann and Schlesinger, "Wiener klinische Rundschau," 1895, No. 5.

of Struempell's. The tumor itself may be fixed in the position it assumes, or it may be freely movable. Its location is usually uninfluenced by breathing, and in this respect it contrasts with tumors of the liver and spleen. It rarely gives a positive dull note on percussion—rather a muffled note. In a certain number of cases no tumor can be detected throughout the whole course of the disease, it is said in 20 per cent. Especially is this the case when the disease is toward the cardiac end. A rotary motion is sometimes characteristic of the tumor.

Toward the end of life *edema of the legs and ankles* often appears, and an intensity of cachexia, which simulates pernicious anemia,—in fact, even furnishes the blood changes characteristic of this affection,—with extreme weakness and death. The *urine* is often scanty, and may give a decided reaction for indican. In a few cases a *febrile movement* makes its appearance, with *chills* and *sweating* at intervals, probably due to intercurrent inflammation. To these symptoms are often added those of *secondary cancer*, especially of the liver, including enlargement of this organ and jaundice. The signs of secondary cancer elsewhere than in the liver should be sought. The duration of cases of gastric cancer is from one to two years; it may be less, especially if the cancer is ingrafted on a pre-existing ulcer. Slow development is said to be characteristic of cases in younger persons.

Diagnosis.—This is generally easy if time and opportunity be allowed for the study of a given case. *Ulcer* is perhaps the disease which furnishes most difficulty, especially as cancer may succeed it. On the other hand, the earliest symptoms of gastric cancer are also those of *gastric catarrh*, which in many cases is mistaken for cancer. The pain and the peculiar intermittent vomiting are the first distinctive signs, and while coffee-grounds vomit may occur whenever moderate quantities of blood are poured into the stomach and mixed with gastric juice, the causes other than cancer are rare. The copious hemorrhage of ulcer gives bright red blood. Bloody vomiting is by no means always present in cancer. To the symptoms described are soon added the emaciation and cachexia, and the palpable tumor more evident after the stomach has been emptied out by vomiting or washing. In the meantime, however, the gastric contents will have been examined, and furnish their quota of information, not pathognomonic, but contributory. Very rarely does it happen that in the vomitus or washings of the stomach we obtain particles of morbid growth whose examination will disclose the structure of cancer.

There is not usually much difficulty in fixing the location of the tumor supposed to be in the stomach. If there is doubt, it may be eliminated in part or altogether by filling the stomach with liquid and noting the effect upon the tumor.

In one instance I mistook *cancer of the gall-bladder* for cancer of the stomach, though I scarcely think it would happen again. The chief reason was because the tumor due to cancer of the gall-bladder was in the situation where the tumor of the pylorus might reasonably be expected to have been. There was jaundice with tenderness in the hepatic region, there were no signs of dilatation of the stomach, and the mistake was scarcely excusable. There is usually less interference with digestion in cancer of the gall-bladder, no mobility of the tumor, and often suppuration with incident fever.

The distinction of gastric from *pancreatic cancer* demands some consideration. The tumor may be in the same position, but in a large proportion of cases of cancer of the pancreas there is jaundice. The tumor of a

pancreatic cancer is often inaccessible. In the latter there are also symptoms of indigestion, like those of gastric cancer, but there is often also diarrhea, and frequently the liquid stools contain oil. Such diarrhea may be checked for a time by ordinary remedies, but in a few days the liquid discharges seem to burst through a barrier which held them temporarily in check. The pancreatic tumor, if felt, is also more immovable.

Tumors of the liver and spleen are continuous with these organs, while the gastric tumor is generally easily distinguished from them by palpation or by an intervening tympanitic area. A *cancer of the transverse colon* may occupy much the same position in the abdomen as one of the stomach, and be also quite movable. The filling of the colon and stomach with water or air may also be availed of in diagnosis. As the growth in the intestine increases, obstruction may result and the tumor increase by the accumulation of fecal matter behind the stenosed portion. A rare complication, increasing the difficulty in diagnosis, is adhesion between the bowel and stomach, restricting motion and possibly causing perforation, through which fecal matter may enter the stomach. Still more difficult, nay, even impossible, in most instances, is the distinction between *duodenal* and gastric cancer. The absence of hydrochloric acid would point to gastric cancer, though such absence, being due to atrophy of the gastric tubules caused by dilatation, may also occur in obstructive duodenal cancer. The acid might also be neutralized by regurgitated bile, regurgitation being favored by the stenosis of the gut. The presence of jaundice would point to duodenal cancer.

Gastric tumors may be confused with *omental tumors*, which may also cause dyspeptic symptoms. But the omental tumor is usually a more nodular, uneven tumor, and is sooner or later associated with peritoneal effusion.

Moreover, every tumor of the stomach is not a cancerous tumor, although most of them are. I have already mentioned my experience with a thickened pylorus associated with gastric ulcer. Such a circumscribed thickening and induration are always possible. We may have the same pyloric stenosis and secondary dilatation. Similar *non-cancerous thickening* may even occur without ulcer. Other forms of morbid growths, such as fibroma, sarcoma, and the like, are too rare to demand notice from the clinical standpoint.

Finally, the gastric tumor is not always demonstrable, and may not be throughout the whole course of its existence. It is said to be absent in about 20 per cent. of cases. Then the diagnosis must be made from the symptoms, especially the rapid wasting and cachexia, which are rarely simulated, even in ulcer. The age of the patient, generally past forty, the deficiency in HCl, and the presence of lactic acid must be allowed due weight. The cachexia of *pernicious anemia* resembles very closely that of cancer of the stomach, and, in the absence of appreciable tumor in the latter, may occasion difficulty. But a study of the blood will in most cases clear up a doubt. The number of red blood-cells in cancer of the stomach is rarely below 2,000,000, while in pernicious anemia it is often below 1,000,000 per cubic millimeter. This difference exists even while the cancerous subject exhibits more emaciation and weakness than that of pernicious anemia. As F. A. Henry well puts it: "In cancer of the stomach the reduction in the number of red corpuscles does not keep pace with the cachexia; in anemia the cachexia does not keep pace with the destruction of cancer." Cancer of the stomach may be latent throughout.

Prognosis.—This is inevitably fatal, but something may be done toward prolonging life by the proper cleansing out of the stomach, the selection and regulation of food, and measures to aid its digestion. The operation of gastrotomy should be considered, as it sometimes prolongs life.

Treatment.—Since the cure of cancer of the stomach is impossible, treatment must be directed toward prolonging the patient's life. I am quite sure that a great deal more can be done than is commonly thought possible. The limit of life of the victim of established gastric cancer does not exceed two years.

The stomach has no use outside of the preparation of the food for absorption. It is not a vital organ in the sense that the heart and the lungs are vital organs. It is important so far as it prepares the food, but if the food can be prepared for absorption outside of the body, its importance is diminished. So it is if we introduce artificially digested food by the rectum. Or we may use both of these methods. We can, by the use of prepared food, diminish the labor of the stomach, and by using the rectum we can, while doing so, relieve the stomach of all labor. This is rendered easier at the present day by the use of peptonized foods of various kinds. The food may be peptonized at home, or the peptonized products of manufacturers may be substituted. First in order of simplicity is peptonized milk. Three to five grains (0.2 to 0.3 gm.) of the extract of pancreas with about 15 grains (1 gm.) of sodium carbonate are added to a pint of milk, and the mixture placed at a temperature of 100° F. (37.8° C.). In one hour all the casein will be peptonized. A curd is first produced, which subsequently undergoes solution. If peptonizing is complete, the addition of rennet will not produce coagulation. Milk thus prepared makes little demand upon the stomach for digestion, and it can be introduced advantageously by the rectum. Peptonized milk has a slightly bitter taste, and unless this bitterness is present, its digestion is unaccomplished. The digestion will take place at a lower temperature than 100° F. (37.8° C.), but it takes longer.*

Beef may be peptonized for rectal alimentation as follows: Take half a pound of beef with the fat removed and a quarter of a pound of fresh pancreas. The pancreas is finely chopped and afterward bruised in a mortar with tepid water at a temperature of 100° F. (37.8° C.). It is then placed in a saucepan, and a raw egg is beaten up and intimately mixed with the meat, previously chopped into small pieces. The product is next allowed to stand at a temperature of 100° F. (37.8° C.) for two hours. It is then strained, after which it is ready for use. This amount suffices for two daily injections. The preparation decomposes very quickly, so that it has to be made fresh every day. I have been surprised at what I have accomplished by this method, which is essentially one recommended by Mayer, of Lyons. In a case where nothing could pass the pylorus, under the use of daily nutritious enemata there occurred each morning an evacuation from the bowel as natural as when the patient was living on a mixed diet and digesting it properly.

The enterprise of the manufacturing chemists and pharmacists has

*The following method, slightly modified from that usually recommended, has been found most satisfactory after numerous trials by patients: Take one pint of skimmed milk, to which add one gill of water. Heat to 140° F. (60° C.)—a temperature at which the finger can be immersed for half a minute. After taking from the fire stir in three grains (0.2 gm.) of powdered pancreatin and 15 grains (1 gm.) of carbonate of sodium. Place in a covered kettle or jug and roll up in a cosy (an ordinary gossamer waterproof coat answers admirably well), near a stove or register to keep warm. Let it remain thus for an hour and a half. It then resembles slightly thickened milk, but there is no curd. Pour it into a covered pitcher, and set aside to cool in the open air. Thus prepared, it has the slightest perceptible tinge of bitterness, and is very palatable.

resulted in the preparation of a number of beef peptonoids and extracts which may be substituted, but I never feel quite so sure of them as of the product made at home, troublesome as its preparation is, because it seems impossible to learn the nourishment equivalent of the manufacturers' product.

However careful the preparation of food, when taken into the stomach in these cases, only a part is used up, and there accumulates gradually a quantity of unabsorbed material which does not pass the pylorus, and to this a copious mucous secretion is added. Hence, occasionally, once a day or every other day, it is desirable to wash out the stomach with water as hot as can be borne, or alkaline waters, as described in the treatment of gastric catarrh. The free use of hydrochloric acid as a medicine also aids not only in the solution of the food ingested, but prevents the fermentations, which contribute irritating acids to the gastric contents and cause further mischief and discomfort.

DILATATION OF THE STOMACH.

SYNONYM.—*Gastrectasia*.

Definition.—A permanent increase in the volume and capacity of the stomach, the result (1) of nervo-muscular atony or (2) of pyloric obstruction. It is to be distinguished from temporary distention and simple large stomach.

Etiology.—(1) The nervo-muscular atony causing dilatation may be the result of habitual overeating, especially food of defective quality, resulting in stasis and fermentation; of excessive drinking, as in beer-drinking employees of breweries; of chronic gastritis; of diseases producing general nervo-muscular atony, such as disease of the spinal cord, pulmonary consumption, anemia, chlorosis, acute fevers, affections of the heart, liver, and kidneys, and other diseases of like import. (2) Mechanical or obstructive dilatation is most frequently due to obstruction from cancer at the pylorus or in the duodenum, or to cicatricial contraction, or to hypertrophic thickening. Such obstruction may also be due to pressure from without, as by cicatricial adhesion or tumor of an external organ or a floating right kidney. It is most frequent in middle-aged persons, but may occur even in children. Tight lacing, by producing dislocation of the stomach and obstruction to the onward movement of its contents, may also be a cause of dilatation.

Acute dilatation of the stomach is a possible, but rare, condition. It may succeed the rapid ingestion of enormous quantities of food and drink. Extreme paralytic dilatation may result, as in two cases described by Hilton Fagge, of which one proved fatal.

Morbid Anatomy.—In addition to the increase of volume the coats of the stomach may be thinned and the glandular structure more or less atrophied. The average normal stomach of an adult holds about 1 1-2 liters (three pints), while the abnormally dilated organ may attain a capacity of three or four liters (six or eight pints), and even more. Where the dilatation is mechanical, there is added the lesion which is responsible for the obstruction.

Symptoms.—The symptoms arising from dilatation are a *sense of*

fullness in the epigastrium, eructations, flatulence, and vomiting, often of enormous quantities. The *appetite* is sometimes poor, at others quite good, and the patient is hungry and thirsty. The *vomited matters* are largely water, but include also remnants of food and every variety of fungus—viz., bacteria, sarcinae, yeast fungi, etc. Their reaction usually exhibits *lessened acidity*, because of diminished hydrochloric acid secretion, but it may be normal or even abnormally acid. Such abnormal acidity is the result of fermentations producing lactic, butyric, and acetic acids. Various gases are thus produced, including carbonic acid and hydrogen. The latter may also arise from decomposition of albuminoid substances, whence too arises sulphureted hydrogen. These fermentations are favored by the absence of HCl, the importance of which in preventing fermentation has been referred to, and by a stasis of the contents in the stomach; for not only is absorption delayed, but the transit of gastric contents into the intestine is also hindered. Indeed, in some cases the stomach is never emptied unless by the tube. Nay, more; it would seem that at times it contains more liquid than was ingested—a possible condition, since the endosmosis of crystalloids (viz., sugar, dextrin, alcohol, and peptones) is attended with the exosmosis of water. From such causes, too, occur *torpor of the bowels, scantiness of urine, and dryness of the skin*.

Anemia, emaciation, and debility sooner or later succeed, and in fatal cases death is commonly preceded by a *drowsiness*, which may be due to the absorption of toxic substances arising in the decompositions going on in the stomach. Dilatation of the stomach is also one of the acknowledged causes of *tetany*, as first pointed out by Kussmaul. The cramps, though often quite severe, are of short duration. They occur chiefly in the muscles of the hands, arms, and legs. Von Leube suggests that this tetany may be due to a “drying out” of the nerves and muscles, but it may also be the result of auto-intoxication. *Unconsciousness* may precede death.

Physical Signs.—These may be elicited by inspection, palpation, and percussion. *Inspection* does not always afford information, but in emaciated cases the greater curvature of the distended organ may be recognized as low as the navel and below, instead of from 1.2 to 2.8 inches above it (3 to 7 cm.). When the stomach is very low, even the smaller curvature may be recognized about two inches (5 cm.) below the ensiform cartilage, uncovering the pancreas. In obstruction of the pylorus the peristalsis from left to right may even be recognized stopping short at the pylorus, where the tumor-like thickening may sometimes be seen. In rare instances a reverse peristalsis, from right to left, takes place.

Palpation may confirm inspection, recognizing the contour of the stomach by its peculiar consistence, which has been compared to that of an air-cushion, but affords little additional information unless there be a tumor at the pylorus which may be felt. Peristalsis, if present, may also be felt, and may be stimulated by filliping the abdominal walls with the fingers, by which also a splashing sound may be produced in the water-laden dilated stomach down as low as the greater curvature. This is to be distinguished from a similar splashing which may be obtained in the normal stomach and adjacent colon, the latter being less constant and less intense.

If a stiff *sound* is used, its end may be felt through the abdominal walls, while the unusual extent to which it may be carried before meeting resistance will attract attention.

Percussion affords the most valuable evidence as to the presence of a

dilated stomach, and in the majority of instances such evidence is conclusive. Auscultatory percussion is especially satisfactory in determining the outlines of the stomach, and the phonendoscope may be used with advantage. Percussion should be made in the standing position, if possible, from above downward, beginning at the edge of the ribs in the neighborhood of the right parasternal line. The note is tympanitic until the upper curvature is reached, when it is substituted by dullness due to the liquid contents, to be succeeded again by tympany of the bowel when the lower border of the stomach is passed. If the patient lies on his back, the dullness disappears and is replaced by tympany. If there is no liquid in the stomach, a change in the pitch of the tympanitic note will indicate the transition from the stomach to the intestine. Further information can be gained by means of the tube, by which the stomach can be emptied and refilled with water and its borders determined by percussion. This is more satisfactory than filling the stomach with carbonic acid gas or air, and even such procedure is not always necessary. If the larger curvature be found by percussion at the navel or below, the stomach is certainly dilated.

No reliable evidence of dilatation is furnished by auscultation.

Diagnosis.—This is usually readily made by attention to the symptoms and physical signs described. Dilated stomach has, however, been mistaken for an ovarian cyst, and abdominal section has been made for its relief.

The question whether the dilatation is dynamic or mechanical—that is, whether it is the result of nerve-atony or obstruction by a tumor at the pylorus—can generally be decided by recognition of a tumor at this orifice. Vomiting is also more severe and frequent, and the peristaltic unrest is more active.

Dilatation differs from falling, or gastropptosis, though descent and dilatation are often present in the same organ. According to Boas, dilatation can be distinguished from descent only when the greater curvature is below the umbilicus, and when the greatest vertical diameter of the stomach is from 10 to 14 cm. (4 to 5 1-2 inches). Different also is enteroptosis, or viseroptosis, which will be considered later.

Prognosis.—When associated with malignant disease at the pylorus, recovery is, of course, impossible, as, indeed, it is in dynamic dilatation, but in the latter case much relief may be afforded to the symptoms.

Treatment.—The most important part of the treatment is *washing out the stomach*, after the method detailed on page 348. This may be done daily, but sometimes it is sufficient to do it on alternate days, occasionally even twice daily. When practiced once a day, it is usually best done on retiring at night, as the stomach is thus freed for the night of irritating material which, if retained, disturbs rest and aggravates the local condition. The patient soon learns the most suitable time for lavage, and when its frequent necessity is determined, he should be taught to perform it.

Of drugs, *hydrochloric acid* is the most likely to be useful, not only because of its importance as a digestive agent, but also as a preventer of fermentation. To this, *pepsin* becomes a useful adjuvant, because it is scantily formed in the dilated stomach. *Nitro-muriatic acid* may sometimes be substituted with advantage, especially when a stimulating effect is desired on the liver. It should be freshly prepared, and from three to five drops of a pure acid should be given to an adult at a dose. *Strychnin* is a drug which has much to recommend it from the theoretical standpoint as

a muscular tonic, and has the further advantage of easy absorption. It should be administered in full doses from a small beginning, 1-30 grain (0.002 gm.) three times a day, increased to 1-20 grain (0.003 gm.) and even more. Extract of *nux vomica* may be substituted, but it is less easily absorbed. Tincture of *nux vomica* is better. It may be given in gradually increasing doses until 30 drops, or 15 minims, are given three times a day.

In addition to the hydrochloric acid as an antiferment, other remedies for this purpose are *charcoal* and *creasote*. The power possessed by charcoal of absorbing gases cannot be utilized, because it possesses this property only in the dry state. Yet it does relieve flatulence and is antiseptic. Such antiseptics may be extended to the intestine. Doses of charcoal of 5 to 10 grains (0.33 to 0.66 gm.) and even more may be given.

Creasote is a useful antiseptic, and may be given alone, in capsule or in pill, in doses of 1-2 grain to a grain (0.03 to 0.06 gm.), or it may be given in sherry wine, whisky or brandy, or tincture of gentian. The following one per cent. solution of creasote is a modification, by George Herschell, of Bouchard's well-known formula :

℞	Creasoti,	10
	Tr. gentianæ,	20
	Vin. xerici,	800
	Sp. vini gallici,	170
	M. et Sig.	One hundred	minims	contain	one	minim	or	one	grain												
		of creasote																			

When the condition is part of the morbid anatomy of cancer of the stomach, only palliation may be expected.

Dietetic Treatment.—Most important is the selection of food in these cases. Solids should be almost totally prohibited, while the typical nourishment is the various kinds of artificially digested food, such as peptonized milk and beef peptonoids. Of the latter, the dry form of beef powder is suitable, because it absorbs some of the excessive liquid sometimes present in the stomach. Beef-juice and rare beef scraped are also easily assimilated, while fatty, and especially starchy, foods are to be used sparingly, if at all.

VISCEROPTOSIS.

SYNONYMS.—*Splanchnoptosis*; *Enteroptosis*; *Gastroptosis*; *Glénard's Disease*.

Definition.—A condition in which, as a consequence of the relaxation of the ligaments of the abdominal viscera, especially those of the stomach, intestines, kidneys, spleen, and liver, these organs fall below their normal position.

Etiology.—An explanation applicable to all cases of visceroptosis has not as yet been made, although several suggestions are more or less applicable. First, Glénard, whose name is so closely identified with the subject that the affection is also called Glénard's disease, holds that a descent of the right or hepatic flexure of the colon, followed by dislocation of the transverse colon, is the primary disturbance in enteroptosis. The hepato-

colic ligament, which is the name he applies to the portion of the mesocolon that approaches the right flexure of the colon, he says is naturally very weak, and can be loosened and stretched by the weight of the transverse colon, particularly when this is loaded with feces. He thinks, too, that debilitating and emaciating diseases or loss of tonicity of the abdominal muscles by repeated pregnancies, by gastro-intestinal auto-intoxication, by exhausting hemorrhage, or by damage to the abdominal muscles by pressure of the clothing, may cause the same condition. The loss of fat in emaciation, however caused, undoubtedly favors its occurrence. When the hepatic flexure of the colon has sunk, the right half of the transverse colon also descends to the point of connection by the tense gastrocolic ligament with the pyloric end of the stomach. At this point the colon becomes kinked, causing stagnation of its contents, followed by dilatation of the colon in front of the constriction. Beyond this it contracts, and, according to Glénard, can be felt as a tense cord. As their ligaments become loosened, the remaining abdominal viscera follow the descent of the transverse colon, the stomach being drawn down by the gastrocolic ligament, the liver and kidneys following. Ewald confirms Glénard except as to the primary factor in the causation of splanchnoptosis. What Glénard regards as the contracted portion of the colon beyond the constriction, and calls "*corde colique transverse*," Ewald believes to be the pancreas. He denies also that simple kinking of the colon, uncomplicated by peritoneal adhesions or by stenosing neoplasms, can cause stagnation of feces. Without assigning a distinct cause, Ewald emphasizes the fact that long-standing dyspepsias and bodily overexertion may create altered relations of pressure and tension, and thus lead to the condition. Landau especially emphasizes disease of the abdominal walls as the primary cause, though cases are reported in which there is no such relaxation. Recent studies are disposed to call into play a congenital factor the action of which may be intensified by any of the various causes named. In late fetal life and early extra-uterine life the position of the abdominal viscera is quite like that characteristic of the disease. This is especially shown by Joseph Rosengart, although Henle and other earlier anatomists described these positions of the viscera in young children. Kussmaul* and Leichtenstern are among those who regard the vertical position of the stomach and colon in adults as a congenital anomaly. The influence of adhesions in producing displacements of the abdominal viscera must not be overlooked, but these are not included in the condition being described.

Enteroptosis is far more frequent in women than in men, 306 out of 404 cases collected by Glénard being women, tight lacing and pregnancy being regarded as the chief causes of this difference in the two sexes. While it is true that the majority of cases met in practice are true visceroptoses, yet it must be admitted that there are instances in which one organ only—as, for example, the stomach, the kidneys, the spleen, or the liver—may be displaced in the manner referred to.

Symptoms.—First of all it must be stated that such a state of affairs as that described may exist without producing any symptoms. The symptoms which are characteristic are, in a word, those of nervous dyspepsia, including derangement of appetite, and especially anorexia, more rarely false sensation of hunger, a sense of fullness in the epigastrium, noisy belching,

* "Zeitschrift für diätetische und physikalische Therapie," Bd. 1, 1898, S. 220.

various bad tastes, and dryness of the mouth. To the fullness in the epigastrium may be added various sorts of pain—shooting, burning, etc.—after eating. There may be constipation or an opposite condition of diarrhea. Hard, scybalous masses may be removed by purgatives or enemas, also mucus in varying amounts, including casts like those in membranous enteritis. The lower portion of the abdomen is distended, and sometimes, in persons with thin-walled abdomens, the dislocated viscera may be recognized by their outlines. Especially is this true if they be dilated with air or gas. By palpation or percussion displacements may be recognized with more or less ease. The transition from stomach to colon can often be recognized by change of note on percussion, while the kidneys, spleen, and liver may be recognized by palpation. Among nervous symptoms may be named general weakness, depression of spirits, headache and fullness of the head, vertigo, and cold feet and hands. There may be palpitation of the heart and disturbed sleep or insomnia. As the result of all this disturbance the patient may become so emaciated as to suggest malignant disease. Chlorosis is often present, and by Meinert is regarded as a constant symptom of the disease; indeed, he holds that gastropptosis is the chief cause of chlorosis in women.

Treatment.—When there are no symptoms produced by this unusual state of affairs, of course no treatment is indicated. When the symptoms are due to displacement, it is evident that mechanical measures or operation are alone likely to be useful in restoring the organs to their normal situation. The former include trusses, pads, and springs, which must be adapted to each case after a study by the instrument-maker with the aid of the physician. In the absence of more elaborate appliances a simple broad bandage may be of service in relieving the symptom. Various degrees of success have been attained by these measures. It is reasonable to suppose that permanent relief can alone be obtained by operation. Treves has reported a case of complete cure by laparotomy and stitching the stomach. Lately, in the Hospital of the University of Pennsylvania, a patient of my colleague's, Alfred Stengel, was operated upon by Alfred C. Wood, with apparent success.

In a stomach thus dislocated there are apt to be atony and sluggish peristalsis, which may result in the accumulation of undigested matters, which are better removed by lavage. Other measures useful in dilated stomach may also be expected to be useful as well as those indicated for nervous dyspepsia.

DISEASES OF THE INTESTINES.

SIMPLE ACUTE CATARRHAL ENTERITIS.

SYNONYMS.—*Acute Intestinal Catarrh; Acute Diarrhea; Acute Ileo-colitis.*

Definition.—The term employed is applied to a diffuse inflammation which generally pervades more or less of the small intestine and the upper part of the large bowel. More circumscribed inflammations are described, and doubtless sometimes occur, but it is not easy to localize them.

Etiology.—The usual causes of simple intestinal catarrh are overeating and excessive drinking, or the swallowing of acid or mineral substances of

an irritating character. Impurities in drinking-water and, in the summer and autumn, unripe fruit are frequent causes. The toxic products of fermented and decomposed food (*leukomains*) are also causes. These sometimes arise inexplicably from substances commonly harmless, such as milk or preparations thereof. Cream-puffs, and even ice-cream, are among these. Irritating minerals are corrosive sublimate and arsenic. Although hot weather favors intestinal catarrhs, especially in infants and older children, they are not so much the direct result of the heat as of its effect in weakening the resisting powers of the child and favoring the decompositions and fermentations referred to. The effect of heat on the nervous system of the very young may reasonably be regarded as a factor in increasing irritability of the gastrointestinal tract or in so diminishing its functional power as to render the ingesta irritating. Cold, or rather a chilling of the body by a fall in temperature, is often followed by enteritis.

Secretion altered in quantity or quality has already been mentioned as a cause of simple non-infectious intestinal inflammation. Much spoken of, but of inferred, rather than of demonstrated, import, is excessive biliary secretion, producing what is known as bilious diarrhea. When such diarrhea is associated with a burning sensation at the anus and with the recognized presence of bile in the stools, the term may be justified, but it is to be remembered that an acid reaction of the alvine dejecta produces a similar sensation. A scanty supply of bile to the intestine, by depriving the gut of the important antiseptic property of this secretion, may also favor the fermentations and decompositions mentioned.

Hyperemia, however induced, favors catarrhal enteritis. Such is the hyperemia secondary to hepatic and cardiac disease, and to inflammation, whether traumatic or infectious, in adjacent tissues, whence it extends by contiguity. Such is the inflammation occasioned by peritonitis, by intestinal obstruction, and the like. Cachectic and anemic states, such as are secondary to cancer, to Addison's disease, and to the last stages of Bright's disease and of tuberculosis, are also favoring causes. Enteritis is also a symptom of certain infectious diseases through their specific poisons, which act directly on the mucous membrane, as in the case of cholera, dysentery, and typhoid fever.

Apart from the effect of nervous influence already mentioned, this cannot be said to cause simple enteritis. It is not unusual for fright and other causes of nervous excitement to produce diarrhea; but this is not the result of an enteritis, but of an increased peristalsis and disturbed vasomotor regulations, and is properly called nervous diarrhea.

Morbid Anatomy.—The morbid changes of simple intestinal catarrh are variously distinct. A hyperemia is naturally to be expected, and in the more decided cases may be manifested by a diffuse redness and injection. It is not often, however, that these are demonstrable. A layer of mucus covering the mucous membrane of the bowel more or less interruptedly is more frequently present. Nor is swelling often evident. At times the solitary follicles are unnaturally distinct, surrounded by a hyperemic circlet. Such enlargements, commonly as distinct as a pin's head, may be as large as a pea, and, becoming filled with pus, form little abscesses, which may rupture, leaving an ulcer. They may extend to Peyer's patches. More rarely chronic ulceration results.

Symptoms.—*Diarrhea* is the most constant symptom of enteritis, involving the part of the intestinal tract named in the definition. The resulting

stools consist of, first, ordinary fecal contents of the small and large intestine, including bile; but, as they continue, they become more and more watery, almost colorless. There may be but two or three, or they may equal twenty or more. They contain more or less mucus, and are often frothy and associated with flatus. With diminished consistence the odor may grow less obnoxious, until totally absent. At other times it is persistently offensive. Minute examination recognizes in these discharges columnar epithelium variously altered, enlarged, granular, and fragmentary, with nuclei obscured or absent, also various non-pathogenic bacilli and cocci, including the *bacterium coli commune*, yeast fungus, crystals of triple phosphate, oxalate of lime, cholesterin, and undissolved food matters. The reaction of the discharge may be neutral or acid.

Next to diarrhea is *pain*, usually colicky, varying greatly in degree; often, indeed, in the milder forms, absent. There is rarely *tenderness*, but palpation may elicit gurgling and the signs of gaseous distention. *Thirst* and *oliguria* are natural consequences of the free discharge of water. There is usually little *fever*, the rise of temperature rarely exceeding one or two degrees, and the higher grades suggest specific inflammation of the bowel. The *appetite*, at first little altered, ultimately fails. Very rarely do the ordinary diarrheas in children and adults terminate in collapse.

It is reasonable to expect modifications of the foregoing symptoms as the result of localized inflammation, as contrasted with those of the more diffuse form just described. Thus, the presence of *jaundice* suggests the probability that the *duodenum* is especially involved. In such cases the urine may also be jaundiced, and there may be added other symptoms commonly associated with jaundice. In the absence of this symptom there is no sign that points to the duodenum as the special seat of the inflammation. On the other hand, jaundice is by no means always present, even if the duodenum is involved. Duodenitis is often associated with acute gastritis, spreading from the stomach—*gastro-duodenitis*.

An acute catarrhal inflammation of the *jejunum* and *ileum*, unassociated with inflammation of the large bowel, would be unattended with diarrhea, the slight acceleration of peristalsis incident to such an event being unlikely to produce this symptom. In this respect, therefore, it will differ. On the other hand, distention of the abdomen, colicky pain, borborygmi, discharge of flatus, and fever continue. Nothnagel has called attention to the presence of little lumps of mucus from the inflamed small intestine in intimate admixture with the contents of the large bowel, often, however, requiring the microscope for its recognition. Even if this be true, however, as v. Leube says, it is scarcely available in practice. Whence it is plain that a diagnosis of an inflammation of this part of the intestinal tract is by no means an easy matter. It is probably also a rare condition by itself. Nothing distinctive is added if only the upper part of the large bowel is involved.

Quite different is it when there is also involvement of the whole of the large intestine—*ileo-colitis*. When this is the case, while the lower down the inflammation, the purer the mucus and the more there is of tenesmus, the mucus remains separate and unmixed with the fecal matter, which may contain undigested particles of food, such as muscular fibers, starch, and fat corpuscles. A diarrhea in which these undigested portions of food are visible to the naked eye is known as *lienteric*. Gmelin's nitric acid test for the biliary coloring-matters ceases in health at the sigmoid flexure, so that if this reaction is obtainable in the liquid discharges, it implies that the exces-

sive peristalsis has affected also the large bowel, by which the bile is carried through with abnormal rapidity. The green stools of children, and more rarely of adults, also indicate a large quantity of bile. Simple feverish states, however, may have the effect also of interfering with the proper digestion of food matters, which may appear in the discharges in consequence. Some information—not, however, too much to be relied upon—may be derived from the seat of tenderness and colicky pains. When these are in the middle or inferior part of the abdomen, they point to the small intestine; when in the upper and lateral parts, to the large.

Diagnosis.—The diagnosis of acute intestinal catarrh is ordinarily easy, by attention to the symptoms previously detailed, including those more or less peculiar to the more circumscribed localities referred to. From *typhoid fever* acute enteritis is usually easily distinguished by its short duration, minor fever, and the absence of the characteristic course the fever takes in the infectious disease, and absence of the spots which so invariably make their appearance on the eighth day in typhoid. The Widal test in the latter disease also aids the diagnosis.

During *cholera* epidemics mild cases of this disease are not recognizable symptomatically from the severer colliquative forms of diarrhea. Under these circumstances, bacteriological examination should be made. The importance of a correct diagnosis will be appreciated when it is remembered that indifference in the treatment of simple diarrhea may not seriously affect the result, while such treatment of a case of cholera, however mild, may result disastrously.

Prognosis.—This is always favorable with prompt and judicious treatment, recovery taking place in from one to three days, as a rule, rarely longer.

Treatment.—Many cases of acute catarrhal enteritis recover under rest and restricted diet, the degree of which necessarily depends on the severity of the case. The simple withdrawal of all food, the substitution of plain milk, or, in severe cases, of boiled milk, for the usual food, generally suffices. A few grains of bismuth subnitrate every two or three hours, fortified with 1-8, 1-4, 1-2 grain (0.0082, 0.015, 0.033 gm.) of opium, or 1-2 ounce (15.5 gm.) of chalk mixture with a fluid dram (4 c. c.) more or less of paregoric may be added. No attempt should, however, be made to lock up the bowel until all irritating matters are removed, and it is often desirable to give an aperient, castor oil being the best, though the unpleasantness of the dose often precludes this valuable remedy. In such event the solution of the citrate of magnesium, Rochelle salts, or Hunyadi water may be substituted. When there is much pain, larger doses of opium may be necessary, especially if hot fomentations, mustard plasters, or turpentine stupes fail to produce the desired effect. When there is elevation of temperature, no better means than the local application of ice can be found to relieve pain. Astringents are rarely necessary, but in the absence of other measures may be used. Tannic or gallic acid in five-grain doses (0.33 gm.) may be given separately or combined with opium.

The various chlorodynes form convenient remedies when there is pain. The dose varies from 20 to 30 minims (1 to 2 gm.). In severe cases, especially when there is nausea, a hypodermic injection of morphin, 1-8 to 1-4 grain (0.0082 to 0.015 gm.), may be given. For the nausea counterirritation by mustard plasters should be used, pieces of ice swallowed entire, while copious draughts of water should be disallowed. Champagne and cold car-

bonated waters may be used for this purpose. The latter may be combined with milk, while the old reliable remedy of equal parts of milk and lime-water should not be forgotten.

CHRONIC CATARRHAL ENTERITIS.

SYNONYMS.—*Chronic Entero-colitis; Ulcerative Colitis; Mucous Colitis; Chronic Diarrhea.*

Definition.—A chronic inflammation of more or less of the large and small intestine, with or without ulceration.

Etiology.—Chronic enteritis may remain after repeated attacks of the acute form, or it may arise *de novo*, however induced, favored by whatever occasions passive congestion. Such favoring causes are diseases of the liver or heart, feeble and anemic states, and the defective nutrition consequent thereon. Chronic exhausting diseases, such as tuberculosis and Bright's disease, may act in this way also. Dysentery is a frequent cause of chronic intestinal catarrh, a remnant of the acute process.

Morbid Anatomy.—The primary condition is that of acute catarrh, and in many cases the morbid changes do not exceed those of acute catarrh, being simply permanent, or later more pronounced. In others, still more decided changes are found, chiefly in the lower part of the ileum and colon. These are mainly ulcerative, but include also discolorations due to hyperemia, blood extravasation and pigmentation succeeding it, thickening of the coats of the bowel, and contraction of partly healed ulcers. There may be stenosis or the opposite condition of dilatation. Such ulceration is distinct from that of tuberculosis, typhoid fever, and syphilis. It may be follicular, as often seen in the diarrheal affections of children, more rarely in adults, or there may be large ulcers or large areas of ulceration. The remnant of mucous membrane is often pigmented and slate-colored, and a pseudo-polyposis sometimes results from contraction. In the small intestine the pigment is apt to be deposited on the ends of the villi and in rings around the solitary follicles, or in their centers, producing the "shaven-beard appearance." The surface of the bowel is more or less covered with mucus and purulent secretion incident to the inflammation. Still another sort of ulceration, from the etiological standpoint, is found at the bottom of saccules of the large intestine in which scybala or hard fecal masses have lain a long time. Ulceration, too, may result, though rarely, from encroachment from without by various kinds of disease of the peritoneum, including cancer, tuberculosis, and the like. Atrophy of the mucous membrane of the bowel is also one of the results of chronic enteritis, not usually recognizable before death.

There may even be atrophy not only of the mucous membrane, with destruction of the glands, but also of all the coats of the small and large intestines.

Symptoms.—These are not uniform. While there is often more or less *diarrhea*, this is as often absent, or substituted by *constipation*, while constipation and diarrhea frequently alternate. More characteristic of the stools is the large amount of *mucous matter* contained in them. This may be present in the shape of "sago"-like masses or "mucous" granules, yellow or brownish-yellow, bile-stained also from the small intestine. Bile-stained

mucus is present only when there is abnormally rapid peristalsis of the large bowel, which causes the mucus to be passed out before the bile is decomposed. Ulceration may be associated with the presence of blood in the stools.

A variety of chronic colitis known as *mucous colitis* or membranous enteritis is characterized by the discharge of large masses of mucus, forming at times complete casts of the bowel. It is more frequent in women, this sex including 80 per cent. of recorded cases, according to W. A. Edwards. It may occur also in children. Its subjects are usually women of the nervous type. It is commonly associated with constipation. At intervals, however, occur attacks of abdominal pain and tenderness, sometimes accompanied by tenesmus and followed by discharges of the mucoid matter referred to. Such attacks may be excited by mental emotion of various kinds. The mucoid material itself seems to be the direct result of an increased activity of the mucous glands, which, with the mucous membrane, are, however, commonly intact after the separation of the large mucous casts. Minute examination recognizes more or less numerous cells, round and columnar, entangled in the mucus, sometimes also cholesterin plates and triple phosphate crystals.

Throughout the numerous attacks nutrition is commonly well maintained, and the woman subject appears plump and well nourished. At other times there are gradual emaciation and ultimate death.

Diagnosis.—This is always easy, except as to the determination of the portion of the bowel involved or the presence of ulceration. Differences in the character of the mucus, as previously noted, will aid in the diagnosis, while the constant or intermittent presence of blood and pus or fragments of tissue in the stools points to the ulcerative condition. Ulceration is sometimes found postmortem where no symptoms were present before death. In the rectum, and, indeed, as high as the sigmoid flexure, ulcer may be recognized by specular examination. Deep-seated ulceration may cause circumscribed peritonitis or may produce abscess. The presence of scybala, surrounded with mucus, points to inflammation of the rectum or colon as far up as its transverse portion. It is not possible to diagnose the presence of atrophy of either bowel.

Prognosis.—The prognosis in all forms of chronic intestinal catarrh is grave so far as recovery is concerned, and treatment avails little in many cases. The disease, however, extends over months, and even years, before the patient succumbs, and recovery is sometimes complete, quite independent of treatment.

Treatment.—As in the case of acute catarrhal enteritis, rest is an important condition of success in the treatment of this disease. Next, we must select a diet with a minimum of waste, so that there may be as little irritating residue as possible. Milk and the albuminous foods are the types of these. Still less irritating must they be if partly digested before being taken into the stomach. Thus, milk may be peptonized, and meat also, and the beef peptonoids of the manufacturers may be employed. It is difficult to ascertain the ratio of nourishing power of these peptonoids to that of solid meat. This, then, should be a fundamental principle of treatment—to furnish a diet with a minimum of waste.

When it is remembered that chronic intestinal catarrh is seated mainly in the large intestine, it is manifest that to reach it with remedies administered in the ordinary way is difficult, and that it is more than likely that such

remedies are absorbed or decomposed before they arrive at the seat of the disease. It is barely possible that after prolonged administration certain drugs, as nitrate of silver, will ultimately reach the seat of ulceration and stimulate it to heal. Such a course must, therefore, be pursued with any remedies thus administered. Nitrate of silver and the sulphate of copper are the two which possess most reputation. The doses are 1-4 grain (0.0155 gm.) of each three times a day, or a smaller quantity more frequently. The acetate of lead may be substituted in doses of two grains (0.132 gm.). The latter is more astringent, but is less likely to excite healing. All these remedies are commonly combined with opium in suitable doses. Subnitrate of bismuth in large doses, 1-2 dram to one dram (2 to 4 gm.), is strongly recommended by some. It undoubtedly diminishes the discharges, but how far it is curative is uncertain.

The natural astringent waters, such as the Rockbridge, and other alum waters in this country, have earned some reputation in the treatment of chronic intestinal catarrh, but improvement under their use is always more marked at the springs themselves, showing that some effect must be ascribed to the change of scene and air and to the salubrious climate of the locality.

Should these measures fail, irrigation of the bowel may be practiced. This is done by means of a fountain syringe, or a funnel in connection with a tube, which is carried high up into the bowel, the patient being placed on his back with a pillow under his hips. The fluids used are solutions of nitrate of silver, sulphate of zinc, and boric acid. At first tepid water, say at 85° F. (30° C.), should be run in very slowly to the amount of two to three pints (1 to 1 1-2 liters). Then solutions of any of the foregoing substances, of the strength of 3 to 4 1-2 parts to 1000, or 1 1-2 to 2 grains to the oz. (0.1 gm. to 0.13 gm. to 30 c. c.) of the more active substances, beginning with the weaker solutions. Salicylic acid may be used in two per cent. solution, boric acid in one per cent. solution, or a one per cent. solution of salicylic and boric acids combined. A one per cent. solution of tannic acid is also recommended, as well as of corrosive sublimate, but the latter is exceedingly irritating and the strength of the solutions should not exceed, at first, 1 : 15,000, which may be increased, if well borne. The nitrate of silver has, on the whole, the best reputation. A preliminary anodyne enema of 30 minims (1 gm.) of laudanum may be given, if needed, or a suppository of extract of opium, say one grain (0.066 gm.). To be effectual, the treatment must be patiently prolonged, especially the dietetic part, and not weeks, but months, of patient perseverance insisted upon. I have already said, in treating of dysentery, that a careful trial of this form of treatment in my hands has been disappointing in its results.

CHOLERA MORBUS.

SYNONYMS.—*Cholera nostras*; *Sporadic Cholera*.

Definition.—An acute gastro-intestinal catarrh, characterized by profuse vomiting, purging, and painful cramp.

Etiology.—The intensity of the symptoms and their similarity to those of true cholera justify a suspicion that a specific organism is responsible for *cholera nostras* as well as for true cholera. No single bacillus has, however,

been settled upon, although the bacillus known as the Finkler and Prior bacillus, which closely resembles the "comma" bacillus of true cholera, is found in the discharges with considerable constancy. The disease may result from toxins generated by a variety of bacilli, but until more definite proof is brought forward, cholera morbus must be regarded as a severe form of catarrhal enteritis associated with gastritis due to some poison generated by the noxious substances causing it. Such are indigestible and decomposed articles of food, unripe fruit, and particularly mixtures of fish, salads and fruit. Especially frequent are these attacks in the hot weather of July and August, though cold and dampness are also regarded as predisposing causes. So are fatigue and a debilitated state of the system. Young adults and persons in the prime of life are more frequently victims than either the very old or very young.

Morbid Anatomy.—This is in no way different from that of catarrhal enteritis, and visible alterations are not always apparent. The same shrunken, ashen appearance of the skin characteristic of cholera may be found in fatal cases of cholera morbus.

Symptoms.—The victim of cholera morbus is commonly seized suddenly, often at night, with *severe cramp, vomiting, and purging*. The first vomitus is the food last ingested, but this is rapidly succeeded by bilious matter, and still later by almost pure water. The same may be said of the bowel discharges, which follow each other in rapid succession—in fact, become at times almost continuous. They present ultimately all the physical characters of the rice-water discharges of true cholera.

The *pain* is at first confined to the abdomen, the paroxysms succeeding each attack of vomiting. Later it extends to the muscles elsewhere, especially those of the calves of the legs.

Corresponding to the loss of water is *thirst*, often intense. The patient is *restless and anxious*. Collapse may supervene, and the *skin become cold, clammy, and ashen-hued, the eyes deeply sunken, the pulse frequent and feeble*. There is not often fever, though the internal temperature is higher than that of the surface. The mind remains clear, even in the event of a fatal termination, almost to the end, when it may become clouded.

Diagnosis.—This was fully considered when treating of cholera, to the section on which the student is referred. The symptoms caused by overdoses of arsenic, antimony, and the poisonous mushroom are similar.

Prognosis.—This is usually favorable, the gravest cases recovering, as a rule. A single night commonly measures the duration of an attack. Fatal cases, however, occur, the very old and the very young being most often victims. Prompt treatment is of the utmost importance, as it will usually cut short an attack which will otherwise last from twenty-four to thirty-six hours and be succeeded by a slow convalescence.

Treatment.—Opium is almost indispensable to the successful treatment of an attack of cholera morbus. The happiest method of exhibition is by the hypodermic needle, more especially because everything given by the mouth is apt to be promptly rejected. For an adult less than 1-4 grain (0.0165 gm.) of morphin is hardly to be thought of. On the other hand, such a dose will often act magically. It should be associated with diffuse counterirritation over the abdomen by mustard, while the hot bath may be added, if the symptoms do not yield.

In the absence of the hypodermic needle, remedies must be given by the mouth. The association with morphin of the hot aromatics, such as

ginger and cloves, seems to aid its retention. Hence the efficiency of the various forms of "cholera drops," the formula for some of which are given under cholera. Chlorodyne is an admirable remedy. Unfortunately, the preparations by different pharmacists are not of uniform strengths. On the other hand, the doses are commonly indicated on the labels, and it is safe to say they may be usually doubled without harm to the patient.

The nausea may be controlled by ice, by cold carbonated waters, by pieces of ice swallowed whole, or by champagne. The latter is particularly appropriate when stimulants are needed, as constantly happens. When there is a tendency to collapse, whisky and ether may be injected under the skin, while enteroclysis and even hypodermoclysis may be needed for the same reasons as in true cholera—the restoration of the water lost from the system.

DIARRHEAS OF CHILDREN.

The importance of these, and some specialization in their symptomatology, demand a separate consideration. Three forms, more or less distinct, are recognizable—viz., acute dyspeptic diarrhea, cholera infantum, and acute entero-colitis.

ACUTE DYSPEPTIC ENTERITIS.

Definition.—An acute inflammation of the small intestine due to diet unsuited to the infant.

Etiology.—The errors in diet referred to do not necessarily consist in unnatural foods substituted for the mother's milk. The latter itself may be altered in quality by emotional causes, by improper food, and by improper hygiene; or the child may be too liberally supplied by overfrequent nursing. Milk itself may be infectious by the presence of streptococcus and tuberculosis infection derived from suppurating and tubercular udders. More often, however, acute dyspeptic enteritis is the result of ingestion of unnatural food, either of substances palpably unsuitable, carelessly allowed, or surreptitiously taken, or of substitutes necessarily employed for mother's milk when she is unable to nurse her infant.

"Bottle food," the most carefully selected, is unnatural, and is probably the most frequent cause of dyspeptic diarrhea in children otherwise well cared for. Two factors in this are active: first, the relatively greater indigestibility of the foods thus supplied; and, second, the bacteria and their toxic products which develop in it before or after ingestion. Normally, the feces of infants contain but few species of bacteria, of which the most important are the *bacterium aërogenes* and the *bacterium coli commune*. The former seems to be an exclusive product of a milk diet, depending upon the milk-sugar for its nourishment, and is found in the upper bowel, where it excites fermentation in milk. The habitat of the *bacterium coli commune* is the lower part of the small intestine and the colon, where it is probably also an agent of fermentation. In infantile diarrhea the number of species of bacteria is greatly increased, but no one or more species has as yet been shown to possess a specific causal effect.

There are also predisposing influences which facilitate the action of the

essential causes. These are, especially, dentition and the extreme heat of summer. The effect of the former is learned in the experience of every mother, while the extraordinary frequency of infantile diarrhea in summer attests the latter. It is evident, too, that constitutional weakness and bad hygiene must also co-operate to diminish the resisting power of infants to other causes. Hence it is that the children of the delicate, the poor, and the unclean suffer most.

Morbid Anatomy.—This seldom exceeds the stage of catarrhal swelling, already described when treating of the enteritis of adults.

Symptoms.—No symptoms may precede the diarrhea, but usually there is in the beginning *restlessness*, with slight *fever*, which seldom becomes high. Such restlessness may be due to *nausea* or to colicky *pain*. The nausea may go on to *vomiting* or not, but *purging* soon occurs. Sudden onset is characteristic. The stools are at first copious and offensive, often yeasty and sour, and generally contain particles of coagulated milk or other undigested food, such as unripe fruit, if the child is old enough to eat it. At first infrequent, they become more numerous, more scanty, acquire sometimes a green color and sometimes contain mucus, rarely blood. In other words the condition passes over into enterocolitis. There may be but three or four stools or there may be twenty or more in the twenty-four hours.

In other cases fever is more decided, and the temperature may rise rapidly to 104° F. (40° C.); there are great *thirst* and *scanty urine*. Even when there is no fever *emaciation* is rapid, and the child falls away amazingly in a few days.

Diagnosis.—The sudden onset and the character of the stools are distinctive and scarcely mistakable. The small amount of mucus distinguishes them from those of ileo-colitis, and the absence of serous discharge from those of cholera infantum.

Prognosis.—This, among the better classes, is commonly favorable, but among the weak, puny, and half-starved children of the poor large numbers perish, especially in hot weather. The disease may pass over into the much more serious affection of entero-colitis.

Treatment.—The principles of treatment are similar to those of enteritis in adults. A primary purge is commonly indicated. Calcined magnesia is very suitable, though castor oil is here also useful. After the purge, bismuth subnitrate or prepared chalk, in doses of 2 1-2 grains (0.165 gm.) for a child a year old, with 1-2 grain (0.033 gm.) of salol as an intestinal antiseptic, may be given every two or three hours. If there is pain, 1-24 to 1-12 grain (0.0027 to 0.0054 gm.) of opium may be added each time or every other dose, as may be demanded by circumstances. An attempt should first be made to relieve pain by gentle counterirritation, as by weak mustard plasters or a plaster of mixed spices, wet in whisky or alcohol, and known as a "spice plaster," and worn continuously. Deodorized tincture of opium or paregoric may be substituted for the whisky. Astringents are seldom necessary in children's diarrhea, but the compound tincture of kino, which contains a little opium, is an efficient remedy, which probably owes much of its efficacy to the latter. Chalk mixture, to which a few drops of paregoric may be added, is an efficient remedy. The pure antiseptic treatment has never commended itself to me, and I am inclined to think that more harm than good has been done by such remedies as resorcin, naphthalin, and the like, which are often irritating.

The regulation of diet is of the utmost importance. It is better to give

the child nothing except a little cold water or barley-water than unsuitable food, while any food that is given should be very much diluted, and should be scanty rather than overabundant. Too much food is often given. Nothing is better than peptonized milk, if the mother's milk or that of a wet-nurse be unobtainable. Plain fresh cow's milk may do as well. All of these should be diluted with Vichy water, lime-water, or plain water, to which a little brandy may be added. As long as casein appears in the stools the milk requires further dilution, or the casein may be removed altogether and the whey only allowed. Animal broths, however dilute, do not find much favor with me, though occasionally beef-juice is well borne when milk has not been, especially in children two or more years old. Albumen water, made by mixing the albumen of one or two eggs with a pint (1.2 liter) of sterilized water, is much more suitable.

The hygienic surroundings of the child are important. Frequent bathing; light, cool dressing in warm weather; and fresh air at all times are indispensable. The patient should be removed from city air to the country or seaside, when possible; and when this is not possible, frequent excursions should be made to the country or on an adjacent river. It is not desirable to keep the child on the lap any more than is necessary.

ACUTE ENTERO-COLITIS.

SYNONYMS.—*Acute Ileo-colitis; Follicular Enteritis; Follicular Dysentery.*

Definition.—An inflammation more severe than dyspeptic enteritis, chiefly of the ileum and colon, affecting especially the lymph follicles.

Etiology.—Enterocolitis is also a disease of the hot months and of teething. It is met, however, in the cooler seasons. It is produced by the same causes as dyspeptic diarrhea. It is more frequent between the ages of six and eighteen months,—second summer,—and is not infrequent in the third and fourth years. It may be a termination of dyspeptic diarrhea or of cholera infantum.

Morbid Anatomy.—The morbid changes are more positive than in acute dyspeptic diarrhea, and are found chiefly in the ileum and colon. In the first stage the mucous membrane is congested and swollen, while the solitary follicles and Peyer's patches are more distinct. The epithelium is exfoliated in places. As the disease continues into the second stage, say after the first week, the enlarged follicles and Peyer's patches become ulcerated. The changes may end here or may become more extensive, constituting the third stage, the ulcers enlarging and deepening to the muscular coat, with the separation of a slough. Or there may be a diffuse infiltration of the bowel with small cells, producing a decided thickening of the same, with more or less obliteration of its distinctive structure. The process may be so intense as to cause coagulation-necrosis—false membrane.

Symptoms.—The disease may begin as a *dyspeptic diarrhea*, also as a *cholera infantum*. It is much more serious than dyspeptic diarrhea, as evidenced by the higher *fever*, which rises rapidly to 104° F. (40° C.), but still remains lower than in cholera infantum. *Vomiting* is less common than in dyspeptic diarrhea or cholera infantum. There are decided abdominal *pain* and a *tense, swollen belly*. The fecal discharges, which are at first painless, are small in quantity and contain much mucus and even a little blood.

They vary in frequency from fifteen to thirty in the twenty-four hours, and occur more frequently during the day. The disease may abate at this stage and convalescence be established, though recovery remains slow. Or the symptoms may increase in severity, the fever persist, and the *stools be painful and small*, consisting mainly of mucus and blood. Commonly odorless, they may also be extremely fetid. The *urine* is scanty, of high specific gravity, and deposits mixed urates. The child wastes almost to a skeleton, the skin becomes loose and flabby, and the "old man" appearance is assumed. Such a case may last five or six weeks, terminating fatally, yet may, on the other hand, get well. A few fatal cases are much more rapid in their course, being ushered in with convulsions and ending in from forty-eight hours to five or six days. Relapses after convalescence are not uncommon, and should be guarded against.

Diagnosis.—Acute entero-colitis is characterized by a greater severity than *dyspeptic diarrhea*, by the high fever, the large amount of mucus in the stools, the greater pain, and the more rapid prostration. From *cholera infantum* it differs in its lower hyperpyrexia, and in the absence of vomiting, of colliquative diarrhea, and of collapse.

Prognosis.—This is more unfavorable than in acute dyspeptic diarrhea; more favorable than in cholera infantum. Recovery is not infrequent after a lengthy illness of four to six weeks, while the severe dysenteric form is apt to be early fatal. Much depends upon the promptness with which treatment is instituted and the ability of the parents to carry it out, and upon the previous vigor of the child, its hygiene, and its food.

Treatment.—The general hygienic and dietetic treatment of acute entero-colitis is similar to that of acute dyspeptic diarrhea; the medicinal treatment is somewhat different. Anodynes are more imperatively demanded, because there is greater suffering, and depletion may be needed in the beginning by salines, though good judgment is required, because the child's strength must be husbanded. Otherwise, drugs are not of much use, though bismuth, in full doses, may be given with advantage.

The colon may be flushed with a one per cent. cold salt solution, or cold water or pieces of ice may be introduced into the rectum, which may also be used for medication, more particularly by opium. I do not think the large rectal enemas recommended in the chronic colitis of adults are to be advised for children. If used, they should be very weak. Solutions of nitrate of silver, one grain to the ounce (0.066 gm. to 30 c. c.), and tannic acid, five grains to the ounce (0.33 gm. to 30 c. c.), are suitable. The mouth should be often examined and, when necessary, the coming teeth scarified, not once only, but as often as necessary.

CHOLERA INFANTUM.

Definition.—A variety of acute catarrhal enteritis of intense severity, corresponding in symptoms and course to cholera morbus in the adult, but much more serious in termination.

Etiology.—The same reasons that lead us to expect a specific cause of cholera morbus would suggest one also for cholera infantum. None has, however, been found. It may reasonably be ascribed to toxins generated in the decomposition and fermentation of foods, since some error of diet is almost always the apparent exciting cause. There are also predisposing

causes, of which hot weather, dentition, or both, bad hygiene, the previous presence of dyspeptic diarrhea or entero-colitis, are instances. It is less frequent than either of the last-named affections, including only a small proportion of the summer complaints of children—according to Holt not more than two or three per cent.

Morbid Anatomy.—There is little, if any, deviation from the normal appearance in the affected bowel.

Symptoms.—These consist in copious *serous stools*, at first containing some offensive fecal matter, later a few particles of greenish matter; but ultimately they are almost aqueous, being ejected also with great force. They contain numerous bacteria, but no constant organism has been found. There is *crampy pain*, and the *limbs are drawn up or rigidly extended*. There is decided *fever*, more than in either of the two other forms, the temperature reaching 105° F. (40.5° C.); the *pulse* is frequent and feeble, while *restlessness* is a characteristic symptom. The temperature should be taken in the rectum, as that of the axilla may be misleading. Indeed, the skin sometimes feels cool when the internal temperature is high. There is intense *thirst*, and the child eagerly drinks water. The purging may come on suddenly or may succeed dyspeptic diarrhea or ileo-colitis. Simultaneously there is severe and obstinate *vomiting*, including bile at first; but later the vomited matter is also serous. The *tongue is coated* in the beginning, but later becomes dry and red. The child rapidly loses strength and as rapidly emaciates. The restlessness is succeeded by *apathy* and *indifference*, and the condition passes into collapse. The eyes become sunken, the fontanelles depressed, the skin gray or ashen and closely applied to the frame, producing an appearance which, once seen, is rarely forgotten. Or the more severe symptoms may subside, and a condition of *torpor* or *semiconsciousness* may supervene. The head is retracted, and there may be *convulsions*; the breathing is interrupted and of the Cheyne-Stokes type; the pupils are irregular; there is clutching of the fingers—in a word, the “hydrecephaloid” state, so called by Marshall Hall, is present. These “brain symptoms” have often misled the inexperienced, but they are not associated with changes in the brain or in its meninges. They may be due to the toxins developed in the intestine by bacteria.

Diagnosis.—This is not difficult. The serous vomiting and purging, rapid emaciation and prostration, and the hyperpyrexia are significant, while the nervous symptoms described as succeeding them confirm the nature of the disease.

Prognosis.—Unless the last-described symptoms supervene, the course is rapid to a fatal termination by collapse in from a few to twenty-four or forty-eight hours. If the hydrecephaloid state is added, the disease may be prolonged a few days more. Recovery is not impossible, and begins with abatement of the more serious symptoms within the first twenty-four hours, followed by tedious convalescence. Or there may be a delusive improvement, followed by a return of the choleraic symptoms, or the disease may pass into entero-colitis.

Treatment.—All that has been said about food in dyspeptic diarrhea and entero-colitis applies here, but the opportunity for its application cannot, indeed, be availed of unless convalescence sets in. The symptoms must be met with the greatest promptness by the same measures described in the treatment of adults, but adapted to the age of the child. Here, too, opiates are indispensable. Even morphin may be used hypodermically with great caution.

One hundredth of a grain (0.00066 gm.) is about the proper dose for a child a year old, and it may be associated with 1-500 grain (0.0001032 gm.) of atropin. This may be repeated in an hour if the symptoms do not subside, at a longer interval if they do. Laudanum or deodorized tincture of opium may be substituted and administered by the rectum in doses of from two to four drops (0.133 to 0.264 gm.) in two drams of starch-water. Minute doses of Dover's powder, say 1-10 grain (0.006 gm.), may be given in combination with bismuth in doses of two grains (0.12 gm.). For the diarrhea that may continue after abatement of the acute symptoms preparations of silver, preferably the oxid, are sometimes of value. They may be combined with opium, the dose of the silver being 1-12 grain (0.0056 gm.), of the opium 1-24 to 1-12 grain (0.00275 gm. to 0.0056 gm.).

The hyperpyrexia must be combated by hydrotherapy—the bath at 80° F., rapidly reduced to 70° F. (26.6° to 21.1° C.); or, if this cannot be done, the child should be wrapped in sheets wrung out in cold water. Sponging is a feeble substitute. Hyperpyrexia is one of the dangers.

Stimulants are indicated, but the difficulty is to secure their retention, Brandy is the best form of stimulant, though iced champagne may be given in small doses often repeated, while the prompt rejection of liquids should not discourage their readministration. Irrigation of the large bowel may be added, using a flexible catheter, which is introduced six or eight inches (2.3 to 2.7 cm.). A pint (0.5 liter) will suffice for a child six months old, and a quart (1 liter) for one of two years. The water may be tepid, or cold if the temperature is high. The one per cent. salt solution may be administered by enteroclysis, and even by hypodermoclysis in extreme cases of collapse. The hot bath should be substituted for the cold in collapse, and strychnin may be administered hypodermically in doses of 1-100 grain (0.00066 gm.) to a child one year old.

Should convalescence set in or entero-colitis supervene, great caution in the giving of food should be observed. Only peptonized milk should be used, substituted occasionally by raw beef-juice, increased, if well borne, a teaspoonful at a time; or dilute egg-albumen may be tried if these are not retained.

THE CELIAC AFFECTION IN CHILDREN.

SYNONYMS.—*Diarrhœa alba*; *Diarrhœa chylosa*.

Definition.—A form of intestinal catarrh of children one to five years old, of insidious onset, and characterized by copious, offensive, loose, frothy stools, resembling oatmeal gruel in color and consistence. It was first described by Gee.

Etiology.—This is unknown. Ulceration of the intestine has been found, but there is no distinctive morbid anatomy.

Symptoms.—The symptoms, in addition to those named, are progressive *wasting* and *weakness*. There is *no fever*. The abdomen is distended as by flatus, but is inelastic and doughy.

Prognosis.—It is commonly fatal. It has been likened to the *hill diarrhea* of the tropics, which affects adults.

Treatment.—This can only be symptomatic.

PSEUDO-MEMBRANOUS ENTERITIS.

SYNONYMS.—*Croupous Enteritis; Diphtheritic Enteritis.*

Definition.—A rare variety of intense inflammation affecting either bowel, and characterized by the formation of false membrane.

Etiology.—Pseudo-membranous enteritis occurs in connection with such infectious diseases as pyemia, pneumonia, scarlet fever, and even typhoid fever; also from the toxic effect of mineral poisons, such as lead, mercury, and arsenic, and during the cachexias which develop toward the close of cancer, Bright's disease, cirrhosis of the liver, and the like, as a terminal infection.

Morbid Anatomy.—The false membrane present varies in extent and depth. It may be limited so as simply to tip the villi and valvulæ conniventes or other folds with a grayish-yellow film, or the coagulation-necrosis may infiltrate a greater depth in flake-like patches, or it may invade the follicles and solitary glands, which may suppurate. To the false membrane is commonly added a hyperemic basis. The deep-seated diphtheritic inflammation found in diphtheritic dysentery is elsewhere described.

Symptoms.—These may be so slight as to be unnoticeable. At other times there are *diarrhea* and *abdominal pain*, but nothing distinctive.

Treatment.—This is symptomatic, and that of the attending and causing disease.

PHLEGMONOUS ENTERITIS.

This is a rare disease, consisting in a diffuse suppurative infiltration of the submucosa, analogous to phlegmonous inflammation of the stomach. It has been found after intussusception and strangulated hernia, and may cause symptoms of peritonitis by invasion of this coat of the bowel, but there are no symptoms by which it can be recognized before death. It has been met in the duodenum.

HEMORRHAGIC INFARCT OF THE BOWEL.

Definition.—Hemorrhagic extravasation in the wall of the small intestine, due to embolism or thrombosis of one or other of the mesenteric arteries.

Etiology.—A warty vegetation from coexisting valvular heart disease may become the embolus, or the latter may arise from the clot in an aneurysm of the aorta.

Morbid Anatomy.—There are congestion, infiltration, and swelling of the jejunum and ileum, and the superior mesenteric artery will generally be found plugged with a clot, which may be preceded by an embolus. The mesentery may also be the seat of congestion and infiltration.

Symptoms.—There may be sudden *nausea*, *vomiting*, *faintness*, *abdominal tympany*, and *pain*. There may be symptoms of *obstruction*, or *diarrhea* with *blood-stained stools*.

Diagnosis.—The condition is so rare that infarction is not apt to be thought of. But should there be valvular heart disease or aneurysm, the sudden occurrence of the symptoms mentioned might suggest this cause.

Prognosis and Treatment.—The prognosis is invariably fatal in severe cases, and though the occlusion of a small vessel may be followed by recovery, there is no treatment which will avail further than to abate the symptoms.

ULCERATION OF THE BOWEL.

What is Meant.—Apart from ulceration symptomatic of typhoid fever, dysentery, tuberculosis, and chronic enteritis, we are not often called upon to recognize this lesion, while its presence is often unattended with any symptoms whatever. The ulceration of typhoid fever, dysentery, and follicular enteritis requires no further reference; nor the peptic duodenal ulcer which was considered in connection with gastric ulcer; nor tubercular ulceration secondary to tuberculosis elsewhere, which may be said to be probable whenever such tuberculosis becomes associated with obstinate diarrhea, uncontrollable or only partly controllable by medicines. Such probability may be confirmed or not by the finding of bacilli in the fecal discharges, to which end cultures should also be made. At the same time it is to be remembered that bacilli found may have been swallowed with sputum, a source more likely if the patient is known to swallow sputum habitually.

PRIMARY TUBERCULAR ULCER.—Occasionally tubercular ulcers occur primarily or without preceding symptoms of tuberculosis elsewhere, especially in children. They are seldom, if ever, below the ileum and appendix vermiformis, yet they do occur in the rectum. There is no way of discovering them during life.

In the first place, such ulceration is hardly suggested unless there is some discharge from the rectum of the nature of diarrhea, or pus, with or without hemorrhage. Given, however, such symptoms, with tenderness in the region of the ileum, decided fever, pronounced emaciation, and a tubercular history, the feces should be examined for tubercle bacilli, the finding of which would be conclusive in the absence of the possibility of their being swallowed. On the other hand, their absence would not exclude tuberculosis. The sago-like clumps of mucus, formerly considered pathognomonic of tubercular ulceration, are no longer so regarded, since they are found in cases where autopsy has established the absence of any ulceration whatever. The presence of enlarged mesenteric glands palpable through the abdominal walls would be a further confirmation. Especially justified would be the suspicion if to the diarrhea the symptoms of circumscribed peritonitis—viz., tenderness, impaired percussion resonance, and perhaps slight fever—are added, or if there are the symptoms of general peritonitis.

A rare, but acknowledged, seat of the tubercular ulcer is the appendix vermiformis, a rupture of which might cause any one of the varieties of perityphlitis and peritonitis due to perforation in appendicular disease, including post-peritoneal abscess invading the neighborhood of the kidney and producing one of the forms of perinephric abscess. A similar termination may follow perforation of any form of ulcer of the bowel suitably situated, as in the posterior wall of the ascending and transverse parts of

the duodenum, and ascending and descending colon. The presence of tubercular ulcer is not incompatible with cicatrization, which may even produce stenosis of the bowel. Tubercular ulcer of the rectum may be recognized by specular examination.

SYPHILITIC ULCER.—Syphilitic ulceration is confined almost entirely to the rectum, and is not very common here. Its possible presence in the colon and ileum is simply to be remembered, as its diagnosis is out of the question. The suspicion of its occurrence in the rectum is justified under circumstances of rectal discharge of blood and pus not due to carcinoma. Syphilitic ulcers arise as primary sores and papules or from breaking down of gummy tumors. They are characterized by their serpiginous outline, an indisposition to heal, and the presence of condylomata about the anus—usually the broad, but rarely also the pointed variety.

EMBOLIC ULCER is another possible variety of intestinal ulcer, though it is not recognizable before autopsy. Embolism and consequent ulcer may happen when valvular heart disease exists or septic pyemia, and it is possible that a branch of an intestinal artery may become the seat of lodgment of an embolus from the heart or from some septic focus, and be followed by necrosis and solution of the area supplied by it.

Treatment.—In addition to the general treatment of tuberculosis, the diarrhea occasioned by the ulceration should be treated by the usual remedies, among which should be included nitrate of silver and sulphate of copper with opium.

The patient with syphilitic ulceration should receive the specific treatment of syphilis, while the ulcer, if accessible, should be treated by local applications of silver nitrate in solid stick.

APPENDICITIS.

SYNONYMS.—*Typhlitis; Perityphlitis; Paratyphlitis.*

Definition.—An inflammation of the vermiform appendix, catarrhal, ulcerative, or interstitial, which commonly extends to the structures lying in contact with it, producing:

1. A peritonitis which is plastic and limited—appendicular peritonitis, or peri-appendicitis.
2. Circumscribed suppuration or abscess—para-appendicitis, or perityphlitis.
3. Septic and general peritonitis.

Perforation and gangrene are often intermediate incidents.

The word appendicitis, which is now by almost unanimous consent applied to the disease under consideration, did not secure the application without a struggle. The term typhlitis, so long employed, was adopted because it was thought that the disease began in the cecum, or typhlon. Modern studies go to show that true appendicitis almost never begins in the cecum, but that in essentially all cases the appendix is the root of the evil. Inflammation and perforation of the cecum are, however, possible events, though they are not clinically separable from appendicitis. It also often

happens that one of the earliest symptoms by which appendicitis is recognized is that of inflammation of the peritoneum covering the appendix and adjacent cecum; but the existence of very positive disease of the mucous membrane of the appendix has been demonstrated over and over again when the peritoneum has not been invaded. It is, therefore, likely that the process begins in the appendicular mucous membrane each time. The term appendicular peritonitis, or peri-appendicitis, is a good one for the inflammation of the peritoneal covering of the appendix, while para-appendicitis or perityphlitis is equally suitable for the more extensive peritonitis about the cecum, and the term perityphlitic abscess indicates well that a similar inflammation has gone on to pus formation.

Historical.—None of the facts bearing on the nature of appendicitis is of very old date, while the correct notion of its nature may be said to have been quite recently established. The first recorded case of perforation of the vermiform appendix appears to have been by Mestivier, in 1759, caused by a large pin in the appendix; another was reported by J. Parkinson, an English physician, in 1812; another by Wegeler, in 1813. In 1824 Louyer-Villermay reported a case of fatal peritonitis which he ascribed to perforation of the appendix. In 1827 Melier reported four cases—three of perforative appendicitis and one of relapsing appendicitis. Melier even suggested the possibility of curing the patient by operation, providing the diagnosis could be sufficiently established. Other isolated cases of fatal inflammation of the appendix were published from time to time, but the first systematic article was prepared by Husson and Dance in 1827, at the suggestion of Dupuytren, and the views promulgated by them were apparently those of the great surgeon himself, since they are the same as those he published six years later (1833) in his "Lectures on Clinical Surgery." He treats of irritation and inflammation of the mucous membrane of the cecum, extending thence to the retrocecal tissue and thence rarely to the peritoneum. The appendix is totally ignored. In 1830 Goldbeck, at the suggestion of Puchelt, of Heidelberg, wrote his graduation thesis, "On a Peculiar Inflammatory Tumor of the Right Iliac Region." He adopted the views of the French authors and called the disease perityphlitis. He also recorded a case of perforation of the appendix with resulting peritonitis. He says, moreover, that in fatal cases of perityphlitis the appendix has been found intact.

In 1831 J. M. Ferrall published a paper, said to have been written several years earlier, on "Phlegmonous Tumors in the Right Iliac Region," in which the cecum is also held to be the primary seat of the phlegmon, which is described as extending thence to the connective tissue behind it, the peritoneum being accorded a minor rôle.

In 1834 James Copland, in his "Dictionary of Practical Medicine," describes what is now known as perityphlitis under the title "Inflammation of the Cecum." He, moreover, recognized the appendix as a possible primary seat of disease excited by foreign bodies in it and terminating in gangrene—a great advance over the views of Dupuytren. John Burne came still nearer the truth in 1837 and again in 1839. Though he wrote on "Inflammation of the Cecum," even in his first paper he speaks of "ulceration of the appendix" set up by foreign bodies, such as raisin seeds, cherry stones, and concretions, of possible perforation resulting in general peritonitis or local peritonitis, with abscess. In his second paper he goes further, and states his belief that all Dupuytren's cases were due to disease of the appendix. He introduced the term *tuphlo-enteritis*.

In 1838 J. F. H. Albers retrograded a little. Publishing a paper on inflammation of the cecum and introducing the term *typhlitis*, which he divides into acute, chronic, and stercoral typhlitis with perityphlitis, he distinguished the latter affection from typhlitis, with which he says Puchelt and others confounded it. But while recognizing the possibility of disease starting in the appendix and going on even to perforation he regarded the phlegmon of the right iliac fossa as more frequently due to disease of the cecum. In the next year Grisolle, appreciating correctly the rôle played by perforation of the appendix in causing the iliac phlegmon and abscess, opposed the teaching of Albers and claimed that inflammation of the cecum would not cause the grave effects ascribed to it, since dysenteric and other well-recognized forms of ulceration of the same structure show no tendency to extend into the neighboring connective tissue. Grisolle, however, as though under the thrall of Dupuytren and the French school, still assigned an important rôle to the cecum.

From this time, however, and, indeed, from the date of Burne's paper in 1837 to the present, appendicitis has been an acknowledged disease; but it has seemed almost impossible, even to this day, to shake off the idea of typhlitis as a responsible factor in the phenomena of appendicitis. Louyer-Villermay in 1840 reported some cases of rapidly fatal inflammation and gangrene of the appendix. In 1843 A. Voltz

published a retrospective paper entitled "Ulceration and Perforation of the Appendix" occasioned by foreign bodies. He concluded that the appendix was the organ at fault in all cases previously published, and apparently for the first time the cecum and retrocecal tissues were ignored.

Simple catarrh of the appendix was first recognized by Rokitansky in 1843 in his classic work on "Pathological Anatomy." He ascribes it to the irritation of fecal matter and to concretions, and contrasts it with the more intense processes of gangrene and perforation. Such inflammation, he says, may become chronic or go on to ulceration. He also refers to the benign effect of inflammatory adhesions in protecting against general peritonitis in the event of subsequent perforation. He still admitted the existence of catarrhal inflammation of the cecum, ulceration and perforation of the latter, with inflammation of the postcecal tissue as a consequence. So G. Lewis in 1856 ascribed the less serious consequences—including, however, suppuration—to typhlitis, while the violent and fatal cases, he said, began with appendicitis, induced always by concretions. In 1858 C. Wister attached further importance to the part of the appendix in producing the symptoms in question. In this year, too, Oppolzer suggested the name *paratyphlitis* for that form of iliac phlegmon which was extraperitoneal: *i. e.*, between the iliac fascia and bone.

Samuel Wilks was one of those who appreciated the rôle of the appendix. Thus in the treatise of Wilks and Moxon on "Pathological Anatomy" in 1875, he says, referring to the terms cecitis, typhlitis, and perityphlitis: "It is not clear, however, that any one particular form of disease is intended by those who make use of these expressions. The cases to which these names are given frequently occur clinically and recover; but when disease in the same region, with similar characters, proves fatal, we find usually some prior morbid process in the appendix rather than in the cecum itself." Also, "the suddenness of the attack of cecitis and the local peritonitis following, even in the large number of cases which recover, all point to the appendix as being the most frequent cause." But he says also: "inflammations of the cecum itself do occur, and apparently are sometimes caused by continuous lodgment of hard feces in this part of the intestines. Such inflammations, by ulcerating the mucous membrane, lead to perforation and local peritonitis, forming fecal abscesses which may discharge inward, but we believe that this is comparatively rare." Dr. Wilks' most recent views are perhaps best expressed by C. Hilton Fagge, who, in his "Practice of Medicine," edition of 1886, says: "Dr. Wilks has repeatedly expressed to me the opinion that in both 'typhlitis and perityphlitis' the disease begins in the appendix, and that variations in the intensity of the morbid process are the real cause of the supposed distinction between them. And so far as I can learn, all the evidence which morbid anatomy affords points strongly in that direction."

C. With, of Copenhagen, was apparently the first to deny pointedly, in 1880, that peritonitis ever originates in typhlitis. In 1883 William Pepper described the "relapsing" form of appendicitis. Reginald H. Fitz, in a timely and exhaustive paper read before the Association of American Physicians in 1886, admitted, as an extreme rarity, a primary perforating inflammation of the cecum with which appendicitis may be confounded. In a second paper in 1888 he concluded, essentially, that the conditions described as typhlitis, perityphlitis, paratyphlitis, appendicular peritonitis, and perityphlitic abscess are varieties of one and the same affection—*appendicitis*.

The text-books published prior to 1892 treat very generally of typhlitis as an important factor in producing the ultimate phenomena of what is now known as appendicitis, unless we except that of Dr. Fagge, already quoted, who, while he uses the word typhlitis, evidently means by it disease of the appendix. Ziegler, in his "Pathological Anatomy" (1885), also uses the word typhlitis for appendicitis. William Osler, in his edition of 1892, says that the terms "perityphlitis and paratyphlitis should be altogether discarded, as the cases are, with rare exceptions, due to disease of the vermiform appendix"; and says also of "typhlitis, or inflammation of the cecum," that it is "a doubtful and uncertain malady, the pathology of which is not known, but which, clinically, is still recognized by authors." In his edition of 1898 he says "the 'iliac phlegmon' was thought to be due to disease of the cecum—*typhlitis*—and of the peritoneum covering it—*perityphlitis*; but we know now that with rare exceptions the cecum itself is not affected, and even the condition formerly described as stercoral typhlitis is in reality appendicitis." William Pepper, in the "Text-book of Medicine by American Teachers" (1894), treats of typhlitis as an affection very much less common than formerly supposed, because "the majority of cases of acute disease in the right iliac fossa are in reality appendicitis."

Five special treatises of great value have been published in English: "The Pathology of the Vermiform Appendix," by T. N. Kelynack, of Manchester, England, in 1893; "Appendicitis and Perityphlitis," by C. Talamon, and translated from the French by Richard J. H. Berry, of Edinburgh, in 1893; "Appendicitis," by George R. Fowler, of New York, in 1894; "Diseases of the Vermiform Appendix," by Herbert P. Hawkins, of London, in 1895; and "A Treatise on Appendicitis," by John B. Deaver, of Philadelphia, in 1896. Hawkins summarizes the situation in the following proposition, to the confirmation of which American surgery has largely contributed: "In fact, it will be generally allowed that a perforating ulcer of the cecum, though it does certainly occur, is of so rare an occurrence that it may be disregarded";

also, "There is ample evidence that appendicular disease is, at any rate, of frequent occurrence; and this frequency, moreover, is sufficiently frequent to justify us in regarding the appendix as the sole cause of all cases of perityphlitis, mild or severe."

As historical points in the treatment of appendicitis may be mentioned the suggestion of early operation by Willard Parker in 1867. Grisolle had made the same suggestion thirty years earlier, and doubtless, as stated by B. Farquhar Curtis,* many such abscesses about to point had been incised, but Parker first suggested this as a systematic treatment. In 1881 Kraussold advocated early operation and was apparently the first in Germany to do so, but made no reference to Parker. In 1882 Noyes reported 100 cases treated by Parker's method of which 90 had been done in the United States. In 1887 R. F. Weir, of New York, strongly urged the early operation, without waiting for adhesions between the pus sac about the appendix and the abdominal wall, and even, if necessary, to open the general peritoneal cavity in order to reach the pus. At the end of 1887 Sands recorded the first successful case of deliberate laparotomy for general peritonitis from ordinary perforation of the appendix, a prior case by Hall in 1886 being rather an accidental one. In 1888 Treves reported a series of cases of operation for chronic appendicitis of the relapsing type. In 1889 Charles McBurney advocated even earlier operation and removal of the appendix before perforation. In addition to Parker, Sands, Weir, and McBurney, Bull, of New York, Murphy and Nicholas Senn of Chicago, Maurice H. Richardson, of Boston, and John B. Deaver, W. W. Keen, and Thomas G. Morton, of Philadelphia, were important coadjutors in placing the operation for appendicitis on its present plane.

Pathology and Morbid Anatomy.—The etiology of appendicitis will be more easily understood if its morbid anatomy is first considered. Modern studies establish the existence of three degrees or stages of appendicitis:

1. Catarrhal appendicitis.
2. Ulcerative appendicitis.
3. Interstitial or parietal appendicitis.

1. *Catarrhal Appendicitis.*—Our knowledge of this is based upon the systematic, minute study of cases which come to autopsy from other causes as well as from operation. In the first or acute stage there is a shedding of the epithelium of the mucous membrane, with detachment, partial destruction, and extrusion of the follicles of Lieberkühn, and some cellular infiltration of the retiform tissue at their base. The lumen of the appendix contains mucus, leukocytes, exfoliated cells, and casts more or less perfect, of the crypts, with granular débris from the same sources. In the second stage the basement membrane is broken and dislocated, the retiform tissue more closely infiltrated with leukocytes, and the internal surface ragged and uneven. In the third or still more advanced degree the mucous membrane is thickened by infiltration with cells. *The most important fact as to catarrhal appendicitis is that all three stages offer vulnerable foci for the attacks of pathogenic bacteria, and starting-points of an infectious peritonitis.* On the other hand, by the union of the opposing surfaces, *obliteration of the lumen* of the tube may take place, by which it is rendered immune against further attacks. A natural cure has, in a word, been effected. The obliteration may be partial, producing stricture, beyond which a cystic distention of the tube in the end nearest the cecum is not infrequent.

2. *Ulcerative Appendicitis.*—In this stage the mucous membrane and submucous tissue are destroyed to various depths, while it may even culminate in perforation. It is often associated with a concretion or a foreign body. The latter is now acknowledged to be much more rare than was formerly supposed. The error was a natural one, owing to the close resemblance of fecal concretions to seeds, grains of wheat, cherry stones, and even date stones, as the result of a gradual molding of shape and loss of water. The concretions are sometimes also the seat of deposit of lime salts. They may be multiple and may be in the appendix a long time without

* "Twentieth Century Practice of Medicine," 1896, vol. viii. p. 434.

producing harmful effect, the patient dying of other causes. The same is true of foreign bodies, which do, of course, occur and include the objects already mentioned. Fecal concretions are found in from 35 to 50 per cent. of cases; foreign bodies in a much smaller number—say 7 to 12 per cent.

3. *Interstitial or Parietal Appendicitis*.—This stage may succeed upon either of the two stages just described, but occasionally it may arise *de novo* by infection along the lymphatics. In the former event it starts in the abraded or ulcerated surface described; in the latter, in the substance of the appendix wall. It is commonly associated with necrosis or gangrene of the wall, but may prove fatal before the necrosis sets in. The appearances vary greatly. They may be limited to a mere point, scarcely visible, and between this and sphacelation of the entire organ there is every intermediate degree. The gangrenous organ is usually enlarged and distorted. The virulence of the appendicular peritonitis is, however, just as great when there is no necrosis. The peritonitis which ensues on perforation of the appendix is virulent, resulting from the invasion of the peritoneum by myriads of bacteria in the fecal matter set free at the time of rupture of the bowel.

The *minute changes* in interstitial appendicitis are as varied as the macroscopic, but Hawkins' summary of three more distinctive stages or degrees may be accepted as nearly correct. The cases which succeed on the catarrhal or ulcerative form are, of course, characterized by the loss of tissue corresponding to the extent of the disease. To these succeed destructive necrotic processes in the deeper structures of the wall. In the first stage of the latter the inflammation is characterized by necrosis of the muscular coats; in the second by suppuration in them; and in the third by their infiltration with leukocytes and inflammatory exudation. The first is, by far, the most common. In all three bacteria are found in the mucous and muscular coats, and all three are followed alike by virulent peritonitis.

The appendix may also be the seat—indeed, is not a very infrequent seat—of *tubercular ulceration*, followed, too, by perforation. I have lately seen a remarkable specimen of this kind in which no symptoms were present before death. So, too, a *typhoid ulcer* may form in the appendix and perforate, with the formation of a tumor mass in the right iliac region. *Follicular abscess* may exist and occasion the usual symptoms of appendicitis. Actinomycosis has also occurred in the appendix, with the formation of retrocecal abscess and metastatic abscess of the liver.

Superadded to these conditions is often a *localized or general peritonitis*, the development of which, in the majority of cases, constitutes the attack of appendicitis. In lesser degrees of the peritonitis (peri-appendicitis) the adhesions which form are limited to the appendix and adjacent serous tissues, limiting the inflammation and acting as a barrier against general peritoneal infection. In higher degrees the inflammation attacks the tissues in relation to the appendix (para-appendicitis), and forms the iliac phlegmon or tumor. This occupies the right iliac fossa and is variously constituted. It may consist of serous and cellular exudation, which mats together coils of small intestine and the cecum, or there may be a massive accumulation of cells and liquid exudate, constituting abscess. Even the latter, as well as the more solid exudate, may be absorbed. On the other hand, the appendicular or perityphlitic abscess may rupture into the peritoneum, not infrequently producing fatal general peritonitis. The amount of pus varies. There may be a dram or two (4 to 8 c. c.), or a pint (a half liter) or more. More commonly there are from two to four ounces (60 to 120 c. c.). The pus is usually

thin and very fetid; at times it is thick, yellow, and odorless. It may be mixed with fecal matter. The pus may have escaped into the bowel, bladder, or vagina, or externally at some point in the abdominal wall,—as the navel or groin, as in a case of my own,—or through the obturator foramen into the hip or thigh. The iliac muscle may be destroyed and the ilium bared. The abscess, usually in the iliac region, may be in the lumbar region, or perinephric, in the true pelvis, or under the liver. These very diverse sites are commonly determined by erratic situations of the appendix. There may be secondary abscesses of the liver by pylephlebitis or portal embolism. These may have all the terminations possible to hepatic abscess.

If general peritonitis supervene, there are added the usual anatomical appearances incident to this condition—flakes of lymph scattered over the intestines, binding the latter together, with pus-cells in varying numbers in the flakes.

Etiology.—*Exciting Causes.*—All three stages of appendicitis described are probably due to the invasion of micro-organisms, while the foreign bodies, concretions, and other agencies to be mentioned are to be regarded as predisposing causes, furnishing the conditions favorable to the operation of the pathogenic bacteria.

A word as to the nature of the organisms which are responsible for the virulent forms at least. The *bacillus coli communis* is a bacterium whose natural habitat is the colon of healthy individuals, cultures of which from the normal colon prove harmless when injected. Yet cultures of this same bacillus taken from cases of virulent appendicitis produce also corresponding virulence; whence it may be inferred that in some way virulence is engendered in an otherwise harmless bacillus. There is good reason to believe that such bacilli may pass from the intestines to the peritoneum through the lymph spaces in an intestinal wall which is simply damaged, as well as through a perforation. Thus, many cases of so-called idiopathic peritonitis, or peritonitis in which macroscopic examination reveals no evident lesion, may still be due to the bacteria of appendicitis from the interior of the tube. This has been actually demonstrated in some cases, and it is not unlikely that it will be found true of all such cases thoroughly studied.

While in most instances the *bacillus coli communis* has been found in pure cultures, pyogenic bacteria have been found associated with it. The most important of these is the *streptococcus pyogenes*; after this the *staphylococcus pyogenes aureus* and the *proteus vulgaris*; so that the existence of more than one possibly infecting species may be admitted. The bacilli of typhoid fever and influenza are possible infective agents causing appendicitis. The same is true of the infectious agent of rheumatic fever, and although I have never met a case of appendicitis traceable to rheumatic fever it is quite as reasonable to believe that an infectious appendicitis may be thus caused as an infectious endocarditis and pericarditis.

Predisposing Causes.—The most important predisposing cause of appendicitis is the appendix itself. An organ without function, and therefore undeveloped and feebly nourished, is correspondingly feebly resistant to all disease. Its anatomy is such that the entrance of irritating matters is easier than their exit, while inflammatory products are not easily evacuated. As predisposing causes, too, must be considered certain influences which formerly were regarded as exciting causes, such as overeating, especially of unwholesome and indigestible food, acute indigestion from any cause, in addition to the foreign bodies and concretions already mentioned. It can-

not be said that the precise mode of operation of such cause is certainly known. It may be that a hyperemia or deranged circulation thus induced produces a condition favorable to the action of incessantly present bacteria. Similar is the effect of fatigue, cold, and traumatic causes, such as blows and contusions.

Appendicitis is a disease of children and young adults. From 50 to 55 per cent. of cases occur under the age of twenty, 30 per cent. between twenty and thirty, 15 per cent. under fifteen. What bearing the fact that the appendix is longer in children and young adults has upon this can only be surmised. Nearly 80 per cent. of all cases occur in males. It has been suggested that this is because the lumen of the appendix is larger in males, and therefore more liable to receive fecal or foreign matters. Attacks have occurred, however, in the first year of life and as late as the seventy-sixth. More cases occur in summer than in winter. Occupation has no effect in exciting it, but after a first attack recurring attacks of appendicitis are more frequent in men who do heavy work, such as porters and carriers, or men who stand on their feet long each day.

Symptoms.—Simple catarrhal appendicitis is often unattended by any symptoms whatever. Indeed, I cannot see how it can cause any recognizable symptoms excepting pain and tenderness. Many cases of ulcerative appendicitis before the peritoneum is reached in the invasion are characterized by a like absence of distinctive symptoms. Other symptoms more or less mild and vague are on this account overlooked. The interstitial variety, including, as it does, a simultaneous involvement of all the tissues, gives rise promptly to serious symptoms. In point of fact, as already stated, appendicitis is known to be present, perhaps in a majority of cases, by the symptoms of the resulting peritonitis, local or general. Though in most instances the first attack is a mild one, yet no one knows at the onset whether this is going to be the case or not. Furthermore, it is often impossible to say when suppuration has taken place. The supervention of general peritonitis is, however, usually attended by unmistakable signs.

The first symptom is invariably pain—*sudden pain*. Its location at first is not constant: it may be anywhere in the abdomen. Most frequently, perhaps, it is in the neighborhood of the umbilicus. At other times it is in the epigastrium; at others, diffuse. It is intermittent, or at least remittent. Usually, within the first twenty-four hours, it settles itself in the right iliac region, where it remains. It may then be mild or severe: more frequently it is moderately severe. Even at this stage—end of twenty-four hours—its location is not always in the right iliac fossa. It has even settled in the *left* iliac fossa, under the liver, or beneath the spleen, anomalous situations for the appendix. This pain is increased by coughing or taking a long breath, or by turning over on the side.

As constant as pain is *tenderness* in the right iliac region, or if the appendix happens to be placed in one of the unusual situations named, it will be in that situation. Rather strong pressure may at times be necessary to elicit it, but usually moderate pressure suffices. Its extent varies. It may occupy the whole lower quadrant of the abdomen, or may extend up to the costal margin and around into the flank, but the seat of maximum tenderness is oftenest a point known as *McBurney's*—a point at the intersection of a line drawn from the anterior superior spinous process of the ilium to the umbilicus and another along the right edge of the rectus muscle. It is from one and one-half to two inches from the anterior superior spinous

process of the ilium. The patient almost invariably assumes the *dorsal decubitus*, often with the right leg drawn up, because of the relief thus afforded.

The third cardinal symptom, if the patient comes under notice sufficiently early, is *rigidity of the right rectus abdominis muscle* and other muscles overlying the focus of inflammation. This may be associated with a slight distention of the entire abdomen. In explanation of the tenseness it may be said that the rectus and other abdominal muscles receive their nerve supply from the seven lower intercostal nerves, while the superior mesenteric plexus gets its splanchnic branches from the same nerves. This primary tenseness, after two or three days, may be substituted by a *tumor*. The latter varies in size and shape, but is more commonly oval and about as large as a hen's egg, with its longer axis parallel with the upper part of Poupart's ligament. It may be much larger, occupying also the whole lower left quadrant and extending upward and backward into the flank, while its shape may be quadrilateral or triangular. It varies in consistence. Its composition has been described in considering the morbid anatomy of the disease.

There is usually *impairment of resonance* to percussion over such a tumor, though less than might at first be expected. This is because we are really percussing over hollow organs, though matted together by exudation. At times, however, there is a duller note, while at others, it may be natural. In the latter event the tumor is small. Indeed, tumor may be altogether absent, but this can never be said of tenderness.

Vomiting is a symptom of more or less frequency. It is commonly regarded as reflex and is variously severe. The matter vomited is first the gastric contents, with the evacuation of which the vomiting usually ceases, though it may recur in the event of perforation or rupture of the abscess. If the symptom is more prolonged, the vomited matter becomes greenish. Many so-called "bilious attacks" of past times have really been attacks of appendicitis.

Constipation is present in a decided majority of cases from the beginning of the attack. It is due to paralysis of the bowel, and may be so obstinate as to simulate obstruction of the bowel, being even attended at times with stercoraceous vomiting. Indeed, appendicitis has often been confounded with obstruction. On the other hand, there may be diarrhea, recurring with each successive attack. There is loss of appetite. The *tongue* at first may be natural, but later becomes more or less coated, and in advanced stages dry.

There is always *fever* at the outset, the temperature 102°, 103° F. (38.9°, 39.4° C.), and even 104° F. (40° C.), rarely higher, after which it gradually falls, reaching the normal in from five to seven days in favorable cases, which terminate in resolution. The pulse-rate corresponds with the degree of fever, but its force and volume vary with the patient's strength. Should suppuration take place, the temperature continues with but slight fall, or may even rise higher (see Fig. 31). *Suppuration may, however, be unattended with fever.*

A sudden fall of temperature does not always mean the establishment of convalescence. Not very rarely the event has a widely different meaning. It means that, instead of convalescence, perforation has taken place. It is extremely important that this fact should be realized. More than once have I known the physician to have been misled by it. The accompanying temperature chart illustrates such a case (Fig. 32). Another even more

unusual explanation of sudden fall of temperature is the rupture of a small abscess into the bowel. Finally, too much stress cannot be laid upon the fact that there may be gangrenous appendicitis in the presence of normal temperature.

Leukocytosis is present in a large number of cases, the white cells often amounting to 16,000 to 20,000. It is an unfavorable symptom. On the other hand, the absence of leukocytosis, like the absence of fever, should not inspire over-confidence, as a lowering blood count is sometimes evidence that nature has given up the struggle.

Fig. 31.—Temperature Chart Showing Temperature Maintained by Abscess after Partial Decline.

The patient was first seen by Dr. C. F. M. Leidy at 9 A. M. on July 16, the first day of the disease, when the temperature was 104° F. (40° C.). It continued the same at 1 P. M. the same day. It then began to fall, and by 2 P. M. the next day reached 102° F. (38° C.). By 4.45 P. M. of the fourth day it had fallen as low as 100° F. (37.7° C.), after which it rose and fluctuated to about 102° F. (38.9° C.), again rose, reaching 103.2° F. (39.5° C.) at 10 A. M. on the seventh day, when the patient was operated on by the late Professor John Ashurst, M. D., and an abscess evacuated, after which the case proceeded to convalescence.

The urine is scanty, as is usual in fever, and quite frequently contains an abnormal quantity of indican. It is rarely albuminous, unless there be high fever, when there may be the small albuminuria characteristic of fever. There are often irritable bladder and frequent micturition.

Fig. 32.—Temperature Chart Showing Misleading Fall to Normal, Incident to Perforation.

The expression of the patient varies with the severity of the symptoms, but seldom exhibits the anxiousness characteristic of peritonitis, unless the latter actually is present in consequence of perforation or rupture of abscess.

Is there any surer information of the event of suppuration than that furnished by the temperature, as discussed? Fluctuation will, of course, be thought of, but this is rarely obtainable on account of the depth and distribution of the pus. The pus may come to the surface and thus be recognized, but not often; and, furthermore, a case that has been allowed to proceed to this degree at the present day has not been properly handled. The rigor

and sweat, such valuable evidences of the occurrence of suppuration under other circumstances, are, as a rule, wanting in appendicitis. Rapid growth of the tumor and the attainment of large size in a short time point to suppuration, but the most valuable sign is *the presence of exquisite tenderness over the focus of inflammation*. Continued high temperature is significant, though it may be wanting. Fully formed abscess has been found as early as the third day. More commonly six to eight days elapse before a diminished tenderness and slight decline of swelling point to this formation. Appendicitis allowed to go on to suppuration—*i. e.*, not relieved by operation—usually terminates by rupture of the abscess into the peritoneum, followed by general peritonitis and death. The event is variously delayed by the extent and toughness of the protective adhesions which may have formed about the abscess. A few abscesses rupture into the bowel, thus saving the patient's life. Two or three cases in a hundred are thus saved. The fecal fistula incident in this termination usually closes eventually, though not always. In rare instances the abscess, especially if deeply situated in the pelvis, ruptures into the bladder. The termination in these cases is less favorable, 50 per cent. being fatal. A few also break through the groin, and are followed by recovery. Lumbar abscess and perinephric abscess must be mentioned as possible terminations, also infiltration of the abdominal walls and tissues of the thigh, pylephlebitis, and hepatic abscess.

General peritonitis may also ensue after perforation of the appendix. The symptoms of the resulting general peritonitis are those characteristic of this disease when suddenly induced by other causes, *viz.*:

1. Diffuse pain, as contrasted with pain localized in the right iliac region—pain of extreme severity.
2. Generally distended and tender abdomen.
3. Moderate fever, succeeded by normal or subnormal temperature, already alluded to as often misleading the physician.
4. Rapid and feeble pulse.
5. Dry and coated tongue.
6. The phenomena of collapse—*i. e.*, cold, clammy skin, feeble pulse, anxious expression, death.

Complications and Sequelæ.—The most important complication is obstruction of the bowels, by which is not meant the obstinate constipation so often met as an early symptom of appendicitis, but a true obstruction, the direct consequence of constriction by adhesions developed in the course of the peritonitis. It is one of the causes of death, as determined by autopsy, while operation frequently discloses conditions which could easily have produced obstruction.

Other complications are hepatic abscess from pylephlebitis, due to thrombosis and even embolism of branches of the portal vein; also phlebitis of the right iliac vein. In abscess of the liver the diaphragm has been perforated, producing empyema and pyopericardium. Pyemic abscesses elsewhere in the system, including the brain and lungs, have also been found in rare instances. Fecal, vesical, and umbilical fistulæ have been referred to. Fatal hemorrhage has also resulted from necrosis of the walls of the iliac vessels. Appendicitis may occur in a hernial sac.

Recurring and Relapsing Appendicitis.—*Chronic Appendicitis.*—These terms are applied to cases of appendicitis which recur after a first attack. The terms are sometimes used interchangeably, but, strictly speaking, cases are *recurring* which repeat themselves at considerable intervals, as

some months or a year or more; *relapsing*, when the attacks are very close—at intervals, say, of one or two weeks, so as to make them almost continuous. In the former, to which attention was first called by William Pepper in 1883, it is reasonable to believe that the patient has recovered in the interval of the peri-appendicular peritonitis, while the appendicitis, catarrhal or ulcerative, has continued, or there exists a cystic appendix as an exciting cause. In the relapsing form it seems likely that there has not been complete recovery in the interval. Certain it is that one attack predisposes to another, so that, in at least 23 per cent. of cases observed, according to Hawkins, and 44 per cent. according to Fitz, it is found that there have been previous attacks. The symptoms of a recurrent attack are the same as those of a primary one. In many cases the interval between the attacks is passed in comparative comfort; in others, there is no small amount of pain or discomfort in the situation of the appendix. The term chronic appendicitis may also be applied to such cases.

Diagnosis.—The diagnosis of many cases of appendicitis is easy, and becomes more so as experience increases. A certain number of cases must be carefully weighed, and in a few diagnosis is extremely difficult. *Sudden pain*, becoming localized, *tenderness*, and *rigidity* in the right iliac region are three symptoms, which, if present, point almost unmistakably to appendicitis. A "lump" or tumor in the vicinity of McBurney's point is less frequently present, though it is often found in many cases, and greatly aids the diagnosis. The cases difficult of diagnosis are those in which these symptoms are wanting or are in unusual situations. But, in truth, these symptoms are less often absent than has been supposed. More frequently they are not looked for, because there is very little to draw attention to them. A rule should, therefore, be made to examine carefully for them in any person subject to gastro-intestinal attacks, however induced and however manifested. It is certain that some cases of so-called catarrhal enteritis are really cases of appendicitis.

Differential Diagnosis.—*Intestinal obstruction* is a condition with which appendicitis has sometimes been confounded. The special symptoms of the various causes of obstruction, whether those of fecal impaction, of strangulation by bands or twists, by intussusception, or by tumor or foreign body, should be recalled. Especially characteristic of obstruction is the absence of fever, unless the patient lives long enough to permit peritonitis to be set up. The pain in obstruction is more intermittent at first, and though, like that of appendicitis, it may be anywhere in the abdomen, it is not likely to localize itself in the right iliac region. The constipation is more complete in obstruction, and even the passage of flatus is usually absent. The vomiting, also, is more severe and persistent, and is more likely to be stercoraceous. There is more general distention of the abdomen, and limited tenderness is less easily differentiated. *Intussusception* occurs more frequently in children younger than those subject to appendicitis, and is often attended with bloody discharges, which seldom occur in appendicitis, while a tumor may often be felt on examination *per rectum*. Strangulation by bands or twists is more common in adults. *Malignant growths* causing obstruction are usually in the left iliac region, although cancer of the cecum is to be remembered as a disease of the right. Its slower development distinguishes it from appendicitis. (See, also, Obstruction of the Bowels.)

Typhoid fever may be confounded with appendicitis, and I have more than once been startled in the course of typhoid fever by the thought that

I might be dealing with an appendicitis, especially when there have been tympany and prolonged tenderness in the right iliac region; but one has, as a rule, only to recall the mode of beginning of the illness, the gradual development of the fever, its greater intensity and peculiar diurnal variation, the spots at the eighth day, to say nothing of the Widal test, to be reassured in the majority of instances. I recall one case of typhoid fever terminating in perforation in which was simulated very closely even the iliac tumor of appendicitis. I may add that I do not think the typical spots in typhoid fever are ever closely approached by anything similar in appendicitis, though the event of suppuration is said to be sometimes indicated by an eruption. On the other hand, there is nothing to prevent typhoid fever and appendicitis from accidentally coinciding.

A question which one would naturally expect to give rise to difficulty is that differentiating between appendicitis and the *pelvic affections of women* when on the right side, such as a suppurating ovarian cyst around a Fallopian tube, or a pyosalpinx. There can be no doubt that before our present accurate knowledge of appendicitis was acquired, numerous mistakes of diagnosis were made.* Many symptoms are identical, but usually the location of the original pain in the appendicitis is not in the pelvic cavity or in close proximity of the uterus, even though it be not at McBurney's point or the right iliac fossa. The appendicial abscess itself is usually limited to the neighborhood of the normal appendix and cannot be recognized per vaginam, while the pelvic abscess can. Should the appendix rupture, as it rarely does, in the vagina, the pus may be recognized by its stercoraceous odor. It should be remembered that appendicitis and pregnancy may be associated. The onset of suppurating ovarian cyst is much more gradual, and the pain more constant and duller. Pyosalpinx is in more intimate relation with the uterus, while the history differs from that of appendicitis.

Many cases of acute appendicitis were formerly mistaken for *bilious colic* and *acute indigestion*, but these are unaccompanied by tumor or tenderness, while the vomiting is more persistent and the vomited matter differs. *Enterocolitis* occasions colicky pains, but there is no hardness or localization, while there is diarrhea with mucous stools. It will be remembered, however, that these symptoms sometimes attend appendicitis, and it should be remembered, too, that gastro-enteritis may be a favoring cause of infection of the appendix, indeed may be an actual cause that is the result of an afferent wave of bacterial invasion from an irritated intestinal tract as suggested by Dr. Arthur J. Patek.†

Ptomain poisoning or food infection may closely simulate the symptoms of appendicitis, by abdominal pain, nausea and vomiting. The patient will, however, have taken food of the kind known to produce such illness, namely, lobster, sausage, ham, canned meats, cream puffs, old ice cream and the like.

In *hepatic colic* the pain is higher up, in the region of the gall-bladder, while jaundice is almost invariably present, and sometimes there is pain under the left shoulder; there is no fever. In *nephritic colic* the pain extends from the lumbar region into the groin and testicle. A *floating kidney* with twisted ureter is movable, as contrasted with the iliac tumor of appendicitis: there is sometimes flattening of the corresponding lumbar region, while sud-

* For evidence of this, see an excellent paper by the late Dr. Paul F. Munde entitled, "Perityphlitis and Appendicitis in their Relations to Obstetrics and Gynecology," published in "Medical News," May 15, 1897.

† "American Medicine," April 1, 1902.

den relief of symptoms, which characterizes the untwist, is altogether peculiar. The presence of blood in the urine under these circumstances is confirmative of renal origin. In *pyonephrosis* there is tenderness in the region of the kidney, as well as pus in the urine. *Perinephric abscess* occasions tenderness in the lumbar region while the pain radiates into the groin, as in nephritic colic. It is to be remembered that perinephric abscess may be occasioned by suppurating perityphlitis, when the position of the appendix is posterior to the cecum.

Appendicular colic, or neuralgia of the right iliac fossa, is a vague condition of pain in this region, which has been ascribed to peristaltic contraction of the appendix, constituting an effort to expel fecal pellets, but of which no proof is afforded, operation in several cases failing to discover anything abnormal.

I think it sufficient for the physician to diagnose the existence of appendicitis without attempting to point out the particular variety of appendicitis, and while I do not deny the possibility of such diagnosis by some, I have known such serious errors to have been made by those claiming such ability that I do not place much confidence in their claims.

Mention should be made of carcinoma of the cecum or appendix as presenting identical symptoms with appendicitis. It has occurred to me to make the diagnosis of appendicitis where operation showed the presence of cancer of the cecum.*

Prognosis.—It is a difficult matter to consider fairly the prognosis of appendicitis, or rather of the peri-appendicitis growing out of disease of the appendix. For if we separate the cases which do not go on to suppuration, recovery is apparently the rule. Thus out of 190 cases collected by Hawkins, none died. Again, of cases treated by section and drainage after suppuration has set in, fully 25 per cent. die; while if general peritonitis supervene, 75 per cent. die. Of cases operated on in the interval between attacks, scarcely 1 per cent. die.

On the other hand, it is impossible to say of any case, however mild, that if left alone it will not terminate in suppuration, while a large number of cases still perish because of imperfect diagnosis and delayed operation. Again, when the difficulties of an accurate diagnosis in the mildest cases are considered, it is not unreasonable to conclude that many cases of supposed recovery were really not cases of appendicitis.

Treatment.—As soon as the diagnosis of appendicitis is established,—indeed, pending its settlement,—a competent surgeon should be associated with the physician, for the reason that in the majority of cases operative treatment is sooner or later demanded, while the hour for such treatment is best settled by daily conference. The course of cases of appendicitis is often very delusive, and the surgeon who operates frequently is likely to have seen more cases than the physician. *The diagnosis being thoroughly established*, operative treatment should be deferred only long enough to determine whether symptoms will subside under rest. If they do not subside, operate at once. If they subside in a degree without disappearing, also operate. If they subside completely in twenty-four to forty-eight hours, and the *attack is a first one*, operation may be deferred until recurrence; then operate at once, or after subsidence of acute symptoms, as may seem best.

* See also a paper on "Primary Cancer of the Tip of the Appendix," by J. Riddle Goffe, "Medical Record," July 6, 1901.

It must be admitted that it is not always easy to lay down a rule as to when operation is demanded, for it is not only that we must know when to operate to save life, but also that we must know when not to operate in cases so severe that operation will be futile; it is due the operation that it should be saved the opprobrium of such futility. Certain it is, too, that in cases in which operation is of no avail death will be hastened by it, the depressing effect of etherization co-operating to hasten the fatal end. Much difficulty is, however, removed when we decide to operate *without undue haste* as soon as the diagnosis is established in all cases, except when operation will evidently be futile. I say without undue haste, for in many cases it is plain that a few days' delay, if the patient is kept at rest, will make no difference in the result; while, if the inflammation is subsiding, a stage is being reached in which operation is even less dangerous, because the united experience of surgeons goes to show that the mortality of operations between attacks is practically *nil*, while that immediately succeeding diagnosis in ordinary cases is nearly so. There can be no doubt, moreover, that excision of the appendix *after* a first attack is a safer procedure than *during* a first or any attack. Even when suppuration has set in it may be safe to delay operation for a day or two while the patient is held quiescent.

When, on the other hand, shall operation be omitted because it must inevitably be followed by a fatal result? In all cases in which there are diffuse septic peritonitis, rapid pulse, leaky skin, constant vomiting, and constipation, operation is generally futile. In such cases saline purgatives and stimulants, diffusible and cardiac, are indicated, and rarely, though rarely indeed, recoveries have taken place.

Whatever preparation is deemed necessary for operation, when decided on, must be directed by the surgeon.

Medicinal Treatment.—Cases must occur, however, in which, from various causes, medicinal treatment is necessary. Operation may be declined even if urgently advised, while rarely a preparative medicinal treatment may be necessary previous to operation.

First of all, *absolute rest* in bed must be insisted upon as the first essential condition of abatement of the inflammation. Many a fatal case would have been saved had this injunction been carried out.

Next, *relief of pain* is demanded. For this purpose opium should be avoided, except in extreme cases. Only when relief cannot be secured by the ice-bag, by hot fomentations, or by mild counterirritants, as mustard or turpentine, may a minimum dose of morphin, 1-12 or 1-8 of a grain (0.005 or 0.008 gm.), be given hypodermically. The objection to opium is well founded, on the ground that it masks the presence of important symptoms which should be open to observation. In cases where operation is from any cause out of the question, counterirritation by repeated blistering may be practiced, and excellent results were reported under the older treatment before operation became common. Of other remedies for the relief of pain, ice is to be preferred to all others, especially if there is fever. Only after the temperature has been reduced to the normal does it sometimes become abnormally low, and then moist or dry heat may be better borne.

The question of the propriety of giving an aperient is a nice one, and must depend, for the most part, on the circumstances and the good judgment of those in attendance. The result may be very happy or mischievous. Cases may be so advanced or severe that a purgative may cause perforation or rupture of an abscess, but in ordinary cases or in those of moderate

severity an aperient may be useful to clear up a diagnosis, while it relieves pressure, depletes the blood-vessels, and diminishes the danger of peritonitis. On the other hand, purgatives should not be aggressive and drastics should not be used. Perhaps a safe rule would be, "If there is doubt, do not purge." The best aperient is castor oil, followed, if necessary, by salines, and of these Rochelle salts or the solution of citrate of magnesium is recommended. If the stomach is sensitive, calomel in divided doses, triturated with sugar of milk, is the best drug. When there is reason to believe that suppuration has set in, no purgative should be given, and, as a rule, operation should be prompt toward evacuating the pus and removing the appendix at the same time. In severe cases even enemata should be avoided, as tending to favor perforation and rupture.

Nourishment should be purely liquid, and of liquid, milk is the best, though animal broths are not contra-indicated. It should not be an object to force food; indeed, only the minimum sufficient should be permitted.

INTESTINAL OBSTRUCTION.*

Definition.—The words intestinal obstruction explain themselves. Obstruction to the descent of fecal matter is the fundamental idea, but the absence of bowel movements is not an essential symptom. For in the course of our studies it will be found that in intussusception, for example, frequent loose bowel movements occur, and that in fecal obstruction they may be present throughout the whole course of the disease, while in other forms of obstruction they are not infrequent at the beginning. Intestinal obstruction is further divided into *acute* and *chronic*, according to the rate of development of its symptoms, the same causes at times producing acute, and at others chronic forms.

Acute obstruction is produced by strangulation, intussusception, foreign bodies, twists and knots, strictures, and morbid growths.

Chronic obstruction is produced also by strictures, morbid growths, and fecal impaction. Intussusception may sometimes cause chronic obstruction.

I. INTERNAL STRANGULATION.

SYNONYMS.—*Constriction of the Bowel; Hernia within the Abdomen.*

Definition.—By internal strangulation is meant stricture of the bowel by inflammatory bands or adhesions, by vitelline remains, omental or mesenteric slits, adherent appendix, and the like.

Occurrence.—This is probably the most frequent cause of acute intestinal obstruction, though intussusception closely approaches it in frequency. Thus, Reginald H. Fitz, in America, found it in 35 per cent. of 295 cases of obstruction, as against 32 per cent. of intussusception; Duchaussoy, in France, in 54 per cent. of 347 cases, as against 39 per cent. of intussusception; while Leichtenstern, in Germany, found it in 35 per cent. of 1134 cases, as against 39 per cent. of intussusception; and Brinton, in England, found

* Reginald H. Fitz's able paper in the "Transactions of the Congress of American Physicians and Surgeons," 1880, Leichtenstern's article in Ziemssen's "Cyclopædia of Practical Medicine," and Frederick Treves' book on "Intestinal Obstruction," 1884, are important modern papers to which I am indebted for much of the matter in this section.

it in 33 per cent. of 481 cases, as contrasted with 54 per cent. of intussusception. The percentages of Leichtenstern, Brinton, and Fitz are astonishingly close, and cannot therefore be far astray.

Etiology.—The causes of strangulation have been carefully worked out by Fitz in his 101 cases, collected from reports since 1880. Of these in 84 the strangulation was caused by *bands and cords*, of which 63 were simple inflammatory bands or adhesions and 21 were vitelline remains, represented by Meckel's diverticulum,* or by the persistent remains of vitelline blood-vessels. Meckel's diverticulum is usually attached by these remains to some part of the abdominal wall near the navel or to the mesentery, or it may be adherent because of peritonitis. The persistent vitelline vessels may themselves be the strangulating cord in the absence of Meckel's diverticulum. Of the remaining strangulations 6 were due to *adherent appendix*, 6 to *mesenteric and omental slits*, 3 to *peritoneal pouches* and openings, 1 to adherent Fallopian tube, and 1 to pedunculated tumor. To these must be added *diaphragmatic hernia*. This was the cause of strangulation in ten per cent. of Leichtenstern's cases, but Fitz found none reported between 1880 and 1888. I reported two cases of diaphragmatic hernia in 1893,† both of some standing, the immediate cause of death being acute strangulation.

The seat of the strangulation is in the small bowel in a decided majority of cases—nearly 90 per cent. In 83 per cent. the strangulated part lay in the lower abdomen, and in 67 per cent. in the right iliac fossa. Seventy per cent. of cases occur in males, and at least 40 per cent. between the ages of fifteen and twenty, the causes in these being inflammatory adhesions twice as often as vitelline remains. Strangulation in early youth is relatively uncommon, and when it does occur, it is usually caused by vitelline remains.

II. INTUSSUSCEPTION—INVAGINATION.

Definition.—In this condition one part of the bowel has slipped into another, always from above downward, and may readily be illustrated by slipping one part of a coat sleeve into another.

The external or receiving portion, known as the *intussuscipiens*, has its mucous surface in contact with the mucous surface of the middle or intermediate portion, whose peritoneal surface is in contact with the peritoneal surface of the internal or returning portion, while the two mucous surfaces of the returning portion are apposed. The internal and middle parts are called the *intussusceptum*. The resultant is a cylindrical tumor which varies from half an inch to a foot or more in length.

The annexed diagram gives a very good idea of the different parts of the tumor. Intussusceptions may occur in any part of the bowel from the duodenum to the rectum, and are named in accordance with the part of the bowel involved: viz., in the order of frequency, *ileo-cecal*, of the ileum and cecum into the colon, carrying the ileo-cecal valve with it; *enteric*, of the small intestine into itself; *colic*, of the colon within itself in any portion of its course, most frequent of the descending colon into the sigmoid flexure; *rectal*, of the rectum into itself; *colico-rectal*, of the colon into the rectum;

* Meckel's diverticulum, a remnant of the omphalo mesenteric duct, through which, in the early embryo, the intestine communicates with the yolk sac, is a finger-like projection from the ileum, usually within eighteen inches of the ileo-cecal valve. The length of this tube is on an average three inches, while it has attained at times a length of ten inches.

† "Transactions of the Association of American Physicians," 1893.

and *ileo-colic*, of the small intestine into the cecum or colon through the ileo-cecal valve. According to Leichtenstern, 52 per cent. only are ileo-cecal and ileo-colic, 30 per cent. are enteric, and 18 per cent. rectal and colico-rectal.

It will be remembered that intussusception is almost, if not quite, as frequent a cause of obstruction as strangulation, under which the percentages were given.

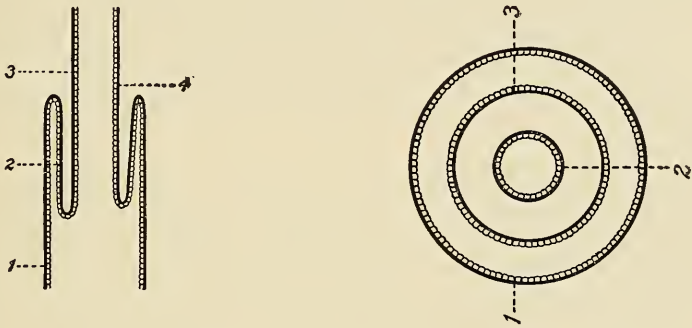

Fig. 33.—Vertical and Transverse Sections of an Intussusception. 1, the Sheath, or Intussusciptiens; 2, the Entering, or inner layer; 3, the Returning or middle layer.

Etiology.—Diarrhea and habitual constipation are probable exciting causes, having preceded in 13 and 12 cases respectively out of 51. Other possible causes are so infrequent as to be unworthy of mention. Experiments with faradism would seem to show, however, that spasm plays a more important rôle than relaxation.

As to distribution, two-thirds are found in males and one-third in females. It is especially an accident of the young, occurring in 34 per cent. under one year and 56 per cent. under ten years.

Intussusception of the dying should be mentioned, in passing, as a form of intussusception which often takes place a short time before death, more frequently in children, and is probably caused by certain irregular peristaltic movements toward the end of life. It produces no symptoms during life.

III. TWISTS AND KNOTS—VOLVULUS.

The majority of cases are axial twists,—*i. e.*, the bowel is twisted on its mesenteric axis,—this being the case in 40 out of Fitz's 42 cases, two only being knots. Eighty-seven per cent. of cases occur in the large intestine, the remainder in the small intestine, one-half are in the neighborhood of the sigmoid flexure, and nearly one-third in the ileo-cecal and cecal region.

It is more frequent in males in the proportion of two to one. Most cases occur between the ages of thirty and forty. It is a disease of the old rather than the young.

IV. OBSTRUCTION BY ABNORMAL CONTENTS OR FOREIGN BODIES.

The majority of these are *gall-stones*—23 cases out of 44 of obstruction by foreign bodies collected by R. H. Fitz; 19 were fecal impactions and

two enteroliths. Obstruction by gall-stones appears to be three times as common in females as in males. They enter the bowel usually by ulcerating through the gall-bladder, commonly into the small intestine, more rarely into the colon.

The seat of obstruction by gall-stones is most frequently the ileocecal region; after this, lodgments are in the small intestine, with diminishing frequency as we ascend. The ages are pretty uniformly distributed from eight to eighty. One of the enteroliths was made up of shellac, found in a man who had been in the habit of drinking alcoholic solution of shellac. Usually, enteroliths are made up of triple phosphate of lime and magnesia, about a nucleus which may be a mass of hair or other foreign body. Courvoisier collected 131 cases, in 70 of which the stone was spontaneously passed *per anum*. Some were very large. In six they were found in diverticula or in the appendix.

In a few instances obstruction is caused by substances introduced by the mouth, but the objects thus introduced, as pennies, buttons, pins, fruit-stones, and the like, are, as a rule, promptly expelled with the stools. In the George B. Wood Museum of the University of Pennsylvania is a plaster cast showing obstruction of the intestine toward its cecal end by plum-stones, followed by inflammation and abscess. A coil of lumbricoid worms has caused obstruction, as has the accumulation of certain medicines, such as magnesia and bismuth.

V. STRICTURES AND MORBID GROWTHS.

A comparatively small number of obstructions occur from these causes. They are always found in adults, four-fifths after the age of forty, and are apparently twice as common in women as in men. By far the largest number is met in the large intestine and lower abdomen, the majority being in the left iliac fossa.

Strictures may be (1) Congenital, illustrated by imperforate anus or defective union between the pylorus and duodenum.

(2) Cicatricial, from healed ulcers. Tubercular ulcers in their healing have produced decided and fatal obstruction, especially in the rectum. Syphilis is also thought to produce stricture in the same locality.

Of morbid growths, the most frequent is the cylindric-celled epithelioma, which may form a ring in the vicinity of the sigmoid flexure, where colloid cancer is also met. Any of the varieties of benign tumors may produce obstruction, while inflammatory processes external to the bowel, especially in the pelvis, may cause obstruction by pressure from without.

VI. FECAL OBSTRUCTION.

SYNONYM.—*Ileus paralyticus vel nervosus*.

Occurrence.—Fecal obstruction occurred 19 times in Fitz's 42 cases. It is more frequent in females and in adults, especially in the aged. It occurs more frequently in the large intestine, and in the lower part rather than the upper. The fecal tumors found in appendicitis are now regarded

as the result of the inflamed appendix, rather than the cause of the cecal inflammation.

Ileus paralyticus may affect both the small and large intestines, but is more common in the latter, especially in the cecum, where the pressure is concentrated from above and below. A local peritonitis may also be developed about the paralyzed and distended intestine. Mention is made under Chronic Constipation of the enormous masses of fecal matter thus accumulated. The wall of the intestine above the accumulation may also be hypertrophied because of the propulsive efforts of the muscular coat.

Etiology.—Fecal impaction is favored by constipation and its causes, although a tendency to fecal obstruction is sometimes congenital. Nervous influence is not to be ignored; the tendency to constipation is seen in the chronic insane, in the hysterical and hypochondriacal, and in affections of the spinal cord. Chronic enteritis and chronic peritonitis favor it; so may anatomical peculiarities of the colon. These causes weaken the muscular coat which moves the contents of the bowel onward, resulting ultimately in an absolute paralysis of a segment of the bowel, arrest of motion of contents, and finally obstruction. The plug of fecal matter grows harder and larger, and compresses and stenoses the adjacent bowel, resisting any further onward movement, and increasing the impediment to the restoration of a natural condition, culminating, finally, in paralysis and stretching of the muscular fibers. The so-called "stercoral ulcer" of the cecum, on which the older writers laid much stress, and which was ascribed partly to gangrene, due to pressure, and partly to the irritating effect of impacted fecal matter, is to-day regarded as extremely rare.

Symptoms of Obstruction.—As most of the important symptoms are common to the different causes of obstruction, I will first consider them from the general standpoint, emphasizing any special relation which a given symptom may bear to a special cause. In addition to the usual absence of bowel movement there is:

First, *abdominal pain*. This is the most constant of all symptoms, being present in a decided majority of cases of obstruction from whatever cause. The pain is one of the earliest symptoms in every form of acute obstruction. It is usually sudden and very severe, and may be intermittent or constant with exacerbations. It may occur in any part of the abdomen, regardless of cause, though most frequent in the neighborhood of the umbilicus, so that its location is of no diagnostic value.

Nausea and vomiting are almost as frequent. The vomitus at the onset consists of the food last taken, but soon becomes bilious, yellow, and finally fecal. Vomiting is relatively infrequent in strangulation and intussusception, while it is relatively frequent in volvulus, stricture, and tumor. The vomitus is especially apt to become fecal when caused by strangulation—usually from the third to the fifth day.

Tympany is next in frequency. It is a symptom of later occurrence than pain and vomiting, presenting itself usually from the second to the sixth day. It varies greatly in degree, increasing as a rule with the duration of the obstruction and being sometimes enormous. It is of least importance in obstruction by intussusception, and most marked in volvulus. It is sometimes, but not always, accompanied by tenderness.

Inability to pass flatus is as constant as the absence of bowel movement.

Tenesmus is a frequent symptom when there is obstruction in the large

bowel, as in 15 per cent. of cases of volvulus and 55 per cent. of acute intussusception. *Fæcal vomiting* succeeds in some cases.

Tumor, under which are included circumscribed visible intestinal coils as well as swelling characterized by absolute dullness, is a rare symptom except in intussusception, when it is characteristic, having been present in 69 per cent. of Fitz's cases, more particularly when in the large intestine, where it is also sometimes associated with a relaxed sphincter. The tumor of intussusception is more frequently found in the left iliac region in the descending part of the large bowel, because the invagination extends in that direction and often does not form an appreciable tumor till that part of the bowel is reached. Tumor occurs sometimes in obstruction by foreign bodies. In strictures, morbid growths, and invagination it may be recognized by rectal examination. Tumors with dullness on percussion are not seen in twist, though visible coils are sometimes present.

Fever is even less frequent than tumor—in fact, its absence is rather characteristic, especially in the beginning. Records of elevated temperature are, however, found in from 22 per cent. to 28 per cent. of all cases, the maximum record being 102° F. (38.9° C.).

Hiccough is an occasional symptom, and appears to be more frequent in volvulus. *Jaundice* is often found in obstruction by gall-stones.

The *urine* has been irregularly studied in acute obstruction. It is not infrequently spoken of as scanty and containing an increased amount of indican, especially in obstruction in the small intestine, not, it is said, of the large. Albumin is rarely present. It is to be remembered that peritonitis causes an increased indican reaction.

Tumultuous peristalsis is not infrequent above the seat of obstruction.

Intussusception especially adds *bloody stools* and *tenesmus*, which are important in the diagnosis, the former occurring in three-fifths of the cases, the latter in 55 per cent. It may occur early or late. Blood-stained stools also occur in connection with cancer of the lower bowel.

Volvulus and *obstruction by gall-stones* add *local peritonitis*, caused, in the latter case, rather by the destructive results incident to the passage of the stone into the bowel from the common duct.

The same train of symptoms may succeed *stricture* and *tumors*, to be followed at times by partial relief, which is again succeeded by similar symptoms leading to ultimate total obstruction and death. Such symptoms will, of course, be associated with the anemic dyscrasia and emaciation which belong to the causing-diseases, and which more frequently lead to death without obstruction than with it. Meteorism in the right inguinal region is said to be more or less characteristic of obstruction by Meckel's diverticulum.

Collapse is the terminal symptom in fatal cases, due to the profound impression on the nervous system, and presents the lowered temperature, leaking skin, and feeble pulse characteristic of collapse from other causes. Cases are reported in which operation during collapse was followed by recovery.

In chronic obstruction due to fecal impaction, more rarely to stricture, cancerous disease, or foreign bodies, these symptoms are less marked and succeed each other more slowly. *In fecal impaction*, what appears to be simple constipation at first is succeeded by permanent retention, which may last for weeks without causing inconvenience. Examination *per rectum* will

often disclose this tube filled with hard fecal matter which may be cleaned out with the finger or a spoon-handle. There may even be *diarrhea*, due to irritation of the bowel above the impaction, when the catarrhal secretion may channel out the mass and carry a portion with it. Gradually, however, the impaction becomes impregnable to all remedies, natural and artificial, the abdomen *swells*, there are *fullness* and *weight* within, and *pain* in the genitals or thigh from pressure on the sacrolumbar nerves; the *appetite* fails, the *tongue* is coated, and the *breath offensive*; sometimes a condition of *lethargy* and *indifference* supervenes along with *great weakness*, and the patient dies of exhaustion. At any time, on the other hand, may follow with suddenness the train of symptoms already described—*pain*, *tympany*, *nausea* and *vomiting*, ultimately of fecal matter, with collapse and death.

In many cases of impaction sooner or later, a *fecal tumor* presents itself—a tumor formed by the mass of retained feces, chiefly in the right iliac fossa, the region of the cecum, corresponding to the outer half of Poupart's ligament. It is sometimes hard, at others soft and yielding, and sometimes tender and painful, probably because of a mild local peritonitis. In the ascending colon the tumor is soft, and in the hepatic flexure it may give rise to the notion of an enlarged liver. It may move in the more loosely attached parts of the colon, and may drag the transverse colon down toward the pubis. In the descending colon and sigmoid flexure it is usually harder, and may be subdivided into scybala. It is, of course, easier of detection in persons with thin abdominal walls, and may be obscured by flatulent distention. When recognized, it is of great diagnostic value. Such tumors have been mistaken for tumors of the stomach, liver, spleen, and kidneys, and for pregnancy.

Diagnosis.—The importance of early and correct diagnosis is intensified at the present day by the fact that operative interference promises by far the best results, while to be effectual it must be early. The diagnosis has three principal objects: first, the existence of *obstruction per se*; second, its *seat*, and third, its *cause*. The first is by far the most important, as operation is indicated in one variety or situation almost as much as in another.

First, as to the *presence of obstruction* in general, the absence of bowel movements, the presence of abdominal pain and tympany are suggestive symptoms. As to differential diagnosis, it has happened that a case of intense *enteritis* has presented all the symptoms of obstruction. Fever is commonly present in such enteritis, while it is absent in chronic obstruction, at least at first. Such a cause of error is, however, rare.

Acute poisoning associated with vomiting, such as is caused by poisonous mushrooms, biliary, renal, and intestinal colic, the pain caused by twisting of the ureter in a movable kidney, all present symptoms more or less like those of obstruction; but the combination of signs necessary to the picture of obstruction is still wanting.

Much more common is the mistaking of *appendicitis* for obstruction. In this there are pain, vomiting, and constipation, as well as tumor in the neighborhood of the cecum, but the differentiation between these two conditions was considered when treating of acute appendicitis. *Peritonitis* itself presents symptoms common to it and obstruction, including abdominal pain, distention, constipation, and collapse, with increase of indican. But the presence of fever, the absence of tumor and of fecal vomiting, point to peritonitis.

The symptoms of *hernia* are also those of intestinal obstruction, and in all cases careful search should be made for a concealed hernia. Such herniæ have been found in the external ring and in the obturator foramen at autopsy by William Osler, who has also met a case of acute hemorrhagic pancreatitis presenting the symptoms of acute obstruction.

Second, as to the *seat of obstruction*. This is more difficult to determine. Unfortunately, the situation of the pain gives little information, since it is almost always in the vicinity of the navel, wherever the actual seat of obstruction may be. In other cases the pain is diffuse. Rarely, it may be at the seat of obstruction. Though fecal vomiting is much more frequent in obstruction of the small intestine than of the large, it still occurs in one-eighth of all cases of the latter.

When a tumor is present, it gives valuable information, being commonly at the seat of obstruction. Active peristalsis limited to one part of the bowels indicates that the obstruction is below it.

Having excluded hernia by a careful examination for a seat of strangulation, examination *per rectum* should be made, also *per vaginam*. By either method a tumor may sometimes be recognized. Especially is this true of a tumor caused by intussusception. A stricture may also be detected by digital examination of the rectum, as may obstruction by foreign bodies.

On the other hand, the rectum may be totally empty of feces and continue so, whence it is probable that the obstruction is in the small intestine or high up in the large. The position and size of the uterus and ovaries may also be ascertained by rectal examination. The rectum can be more thoroughly explored by suitable specula in the knee-elbow position, but rectal exploration by the entire hand has not been followed by the results anticipated. The hard rectal tube has produced perforation, while the flexible tube so coils itself up as to be valueless in diagnosis. Sometimes, if the distended intestine is filled with hard fecal matter, it can be felt as an uneven mass in the course of the bowel.

Moderate distention in the upper part of the abdomen, with flatness below and in the sides, rapid collapse and oliguria, point to obstruction in the duodenum and jejunum. Such distention is temporarily diminished by vomiting, but is uninfluenced by fecal discharges secured by enemas. Nor is the vomiting always fecal in duodenal and jejunal obstruction; when the obstruction is in the ileum and cecum the distention is more central, the region of the colon being flatter until covered in by the extending tympany, and the vomiting is more likely to be fecal.

When obstruction is seated in the colon tympanitic distention is greatest, yet the difference between it and that of obstruction in the ileum is not so great as to possess much diagnostic value. If in the lower colon, there may be tenesmus and discharge of blood and mucus. Measuring the capacity of the large bowel by air, gas, or water has been recommended as an aid to diagnosis. Reliable observation goes to show that these substances may be made to pass the ileo-cecal valve. Water recommends itself so far above the others that it alone will be considered. Moreover, the difficulty in passing water through the ileo-cecal valve is so great that it is practically applicable only in case of the large intestine. The capacity of the large intestine of adults is about six quarts, or about as many liters. That of infants appears to be widely different in children of the same age. Thus, in measurements by Dr. Muir, the capacity of the colon of a boy five months

old was found to be but ten ounces (300 c. c.), while, in a girl of seven months, it was thirty ounces (900 c. c.). If the method is employed at all for diagnosis, it should be early, before the nutrition of the bowel has suffered, since rupture has taken place under light pressure. The patient, etherized, should be inverted or placed on his right side, and precaution taken to keep the fluid from returning. Close pressure of the buttocks generally suffices. The fluid is most conveniently introduced by the fountain syringe, by which pressure can be varied, but the reservoir should not be more than 2 1-2 feet (0.75 m.) above the body of the child. Various difficulties, more or less well founded, are suggested, such as resistance by voluntary muscles during life, valve-like obstruction, which permits ascent of fluid, but not descent, and unequal dilatation. However, the method should not be overlooked, and it is more than likely that much will be learned from future opportunity. Thus, since a case of obstruction at the sigmoid flexure, cited by Treves, permitted the injection of three pints of fluid (1.4 liters), it is evident that only in the event of the injection of a larger amount can the gut be considered open at this point. Treves claims, too, that the entrance of fluid in the cecum may be recognized by auscultation. Under favorable circumstances—as, for example, with empty colon, a trained ear, and skillful technique—this seems quite possible.

Third, the presence of obstruction being recognized, the *nature of the obstructing cause* may sometimes be determined with a degree of probability. First to be considered is the relative frequency of the different morbid states. Adopting Fitz's figures, strangulation and intussusception together make up 70 per cent. of *all* cases, the two being nearly equal. After that come volvulus with 15 per cent., gall-stones with 8 per cent., and stricture or tumor 6 per cent.,—that is, the twists about equal obstruction from gall-stones and tumor and stricture together.

Again, if the obstruction be found in the *large intestine*, it is more likely to be intussusception, twist, or stricture and tumor, since of the obstructions in the large bowel 51 per cent. are intussusception, 30 per cent. twists, and 12 per cent. stricture and tumor. If in the *small intestine*, it is most likely strangulation or gall-stone obstruction, since 72 per cent. of obstructions in the small intestine are strangulations and 14 per cent. gall-stones, leaving 8 per cent. only for intussusception, 5 per cent. for twists, and 1 per cent. for stricture and tumor. If the attack has been preceded by one of jaundice or by other liver symptoms, as hepatic colic, it is almost certain to be gall-stone, especially if the patient be over fifty years old.

If the patient is under thirty, particularly if a child, it is more likely to be *intussusception* than twist, while if there are palpable abdominal tumor, bloody stools, and rectal tenesmus, the case is almost sure to be intussusception, rendered still more likely if the rectum has a large capacity for water, since the intussusception is found near the cecum in 75 per cent., while twist is found near the sigmoid flexure in 50 per cent. Of all forms, intussusception presents the clearest clinical picture and is most easily recognized.

Twist, cancer, and stricture are more apt to be below the sigmoid, and the last two may sometimes be felt by the finger. In point of fact, twist in the large bowel is not often recognized. It is a disease of the adult, rarely occurring under forty; vomiting is less early and less severe than in strangulation by bands. Pain is often severe in twist. Some degree of local

peritonitis almost invariably results, causing rigidity of the abdomen, while meteorism appears early and is extreme, the distended intestine often displacing the solid viscera.

If there is a history of previous peritonitis, *strangulation* becomes more likely, since such inflammation precedes in 68 per cent., while there is also a history of previous attacks in 12 per cent. The pain in strangulation is early, sudden, and severe, and the same may be said of vomiting. It becomes stercoraceous in 60 per cent., while the vomiting affords no relief. There is little or no distention unless peritonitis supervene. There is great prostration, and no tenesmus or discharge of blood. The average duration is about five days. The presence of *diaphragmatic hernia* as a cause of internal strangulation must not be overlooked; it is almost always the result of severe injuries. The half of the thorax containing the viscera is distended and tympanitic on percussion, while breathing movement is restricted, the breath-sounds are feeble, the vocal fremitus and vocal resonance diminished or absent—signs shared with pneumothorax. The pitch and intensity of the percussion note vary also with the degree of distention and the position of the viscera invading the thorax, while there may be metallic tinkling of fluid in the intestine, due to peristalsis.

Obstruction by Meckel's diverticulum is said to be indicated by meteorism in the right inguinal region.

Fecal obstruction is recognized by the symptoms already described under chronic obstruction, and such recognition is not very difficult, especially if the fecal tumor is found. Sometimes, however, on account of its insidiousness, fecal obstruction is overlooked when presenting only the more chronic symptoms, and the patient dies of supposedly unknown cause when accurate and careful study would have led to its discovery.

Prognosis.—In fecal tumors alone, of all the causes of obstruction considered, is the prognosis favorable if the condition is recognized sufficiently early, while a considerable latitude of duration may also be allowed.

Treatment.—In intussusception and fecal impaction alone is it worth while to consider anything but operative treatment.

Treatment of Intussusception.—It is usual to attempt to reduce an intussusception by inflation or irrigation. The latter is preferable in the colic variety, because pressure can be more accurately graduated, but it is considered of little or no value in the enteric form. For the latter Nicholas Senn considers that better results may be obtained by inflation with a gas like hydrogen, which he finds passes through the ileo-cecal valve under a much lower pressure than a fluid. On the other hand, D'Arcy Power recommends that the abdomen be opened at once when this condition is suspected. If irrigation is decided upon, the fluid—salt solution at 100° F. (37.8° C.)—is best allowed to pass into the large intestine slowly by its own weight through a long tube carried high up, the reservoir being raised not more than 2 1-2 feet (0.75 meter) above the etherized patient. A higher level than this for the reservoir may result in rupture of the bowel, while the bowel may also kink if the fluid be allowed to enter too rapidly. Some place the patient head downward over the back of an inverted chair, suitably covered with a bolster and quilts. Others hold that inversion is unnecessary. The nozzle should be closely fitted to the anus, accomplished by simply compressing the buttocks. One hand should be kept flat on the abdomen, while variations of pressure should be avoided. It is said that in this way water may not only be passed from the colon through the ileo-cecal valve into the small intestine,

but also through the pylorus into the stomach, thence into the esophagus, and out at the mouth. If success is not attained in forty-eight hours, it is not likely to follow, and laparotomy should be done. The extent or size of the intussusception furnishes no reason against the use of the treatment. It has been found effectual in 33 out of 44 cases of suspected or probable intussusception collected by Fitz, and therefore merits a trial. Unfortunately, there is always a tendency to recurrence after the reduction of an intussusception by this method. Should the recurrence persist, laparotomy should be done without much delay, especially in view of the fact that the operation is so much better borne early in the disease, before the strength of the patient is exhausted. Rarely should more than forty-eight hours be allowed to elapse without operative interference in cases of acute obstruction from any cause except fecal impaction.

What else may be done early and without risk to the patient? Above all, give *no aperients*. To relieve the excessive vomiting after the simpler remedies have been tried, the *stomach* may be *washed out* as suggested by Kussmaul and described on page 348. This is at once a harmless measure and may be efficient for the purpose intended. It may be done three or four times a day. It may be expected to be of service in the vomiting of any variety of obstruction. *Opium* may be administered hypodermically to allay the intense pain, and may also relieve the vomiting. Or it may be given with a view to cure, which there is reason to believe it has accomplished in cases of intussusception and even strangulation. Opium may, on the other hand, be harmful, by obscuring diagnosis and producing an appearance of relief, while the local condition of the bowel is really growing worse.

The *nourishment* of the cases demands careful thought. It is irrational to continue the administration of nutriment by the mouth when it is rapidly rejected. If the obstruction is in the small bowel the rectum should be the only route employed, while ice should be administered freely by the mouth. On the other hand, when the obstruction is in the colon, when tenesmus and diarrhea are symptoms, and when vomiting is a less prominent symptom, small amounts of liquid nourishment may be introduced by the mouth.

Treatment of Fecal Tumor.—The situation is altered when a diagnosis of fecal tumor has been correctly made. Here nothing is so efficient as *repeated large injections* of warm water, high up and retained for from ten to fifteen minutes if the patient can retain them, as he should be encouraged to do. Good results are sometimes obtained from the coincident use of small doses of calomel, 1-8 to 1-5 grain (0.008 to 0.013 gm.), given hourly. If the fecal impaction is low enough down in the rectum, in most cases the finger or some mechanical appliance, as a spoon-handle, can be used to loosen it.

It is in this form, too, that *electricity*, *massage*, and *metallic mercury*, as used by the older practitioners, are sometimes useful. Electricity is variously used, but the most efficient application is the recto-abdominal, in which one electrode of a faradic machine is placed in the rectum, the other over the abdomen. The use of metallic mercury has been revived by M. Matignon in fecal impaction with apparently good results, the dose being 1.5 to 9 ounces (50 to 280 gm.). It probably acts by insinuating itself in a state of minute subdivision through the fecal tumor and between it and the bowel, loosening and breaking up the mass so as to restore the natural passage. It is of no use when there is strangulation, intussusception, or volvulus.

In stenosis of the gut, inflammatory or otherwise, the treatment recom-

mended for fecal impaction may oftentimes be used, with the effect of removing the obstruction so far as due to the delay of fecal matter at the narrowed point. Sooner or later operative interference becomes necessary.

Twist, strangulation by bands and obstruction by gall-stones can only be relieved by operation, and a surgeon should be associated in the treatment from the outset.

For treatment of *cancer of the bowel* see section on that affection.

CONSTIPATION.

SYNONYM.—*Costiveness.*

Definition.—Unnatural retardation or delay in the natural evacuation of the bowels.

Though there may be some exceptions, an evacuation of the bowels once in twenty-four hours seems to be nature's law in the case of the adult human being, and any prolongation of this interval may be said to constitute costiveness. A popular application of the term is also, however, to a condition in which, though there may not be infrequency of stools, the dejecta are dryer and harder than natural and are discharged with more or less difficulty and pain. The physician should appreciate this, otherwise misunderstanding may arise as to the exact meaning of the patient. Constipation is also something different from retention due to obstruction by various causes. The interval between bowel movements in constipation varies greatly, ranging between a couple of days and weeks. Many constipated persons have no dejections unless aperient medicine is taken.

Morbid Anatomy.—There are no morbid changes characteristic of constipation. Dilatation of the colon in various degrees is present, sometimes enormous, as shown in Fig. 34, and there may be found the remnants of inflammatory or other local lesions which may be responsible for the obstruction. The large accumulations of fecal matter found in these cases are known as *coprostitis*.

Etiology.—The immediate causes of constipation are:

1. Atony of the colon, whence results a slow peristalsis. Perhaps the most common cause of atony is a habit, engendered through indifference or necessity, of disregarding nature's call for relief. Repeated disregard of such call results sooner or later in disappearance of inclination. Sedentary habits co-operate to produce such disinclination. Atony may also be the result of disease of the bowel and of general disease causing debility, such as anemia, chlorosis, and protracted illness, like typhoid fever.

2. A deficiency of the natural stimuli to peristalsis afforded by various secretions, especially the bile.

3. A loss of muscular power in the abdominal walls from overdistention or obesity.

4. Improper food. The foods which most stimulate peristalsis are vegetables, especially those with an insoluble residue, such as is afforded by the outer coatings of grain. Foods of an opposite kind are represented by milk and the farinacea.

5. Finally, stricture and displaced organs,—such as the uterus,—tumors.

and foreign bodies impinging on the bowel and delaying the descent of the feces, become causes.

Among consequences of fecal impaction are hemorrhoids, which result from pressure on the hemorrhoidal veins.

Treatment.—Every case of constipation should be carefully studied with a view to determining its cause, and if such cause is found, it should, of course, be removed when possible. If such cause is not found, the first injunction in the management of constipation is the observance of *regularity in going to stool* at a fixed hour of the day, whether inclination prompts or not. The usual hour for this purpose is immediately after breakfast, though it matters not much when it is, so that it is regularly observed. Especially harmful is it to disregard any inclination which may appear at this time, or, indeed, at any time. Next is the use of *food* of the kind referred to under the head of etiology, such as fresh green vegetables of all kinds and succulent fruits.

Of breads, the so-called "brown" or bran bread, or gluten bread, is to be preferred. With such food should be conjoined massage of the abdomen or compression, either by the patient himself or by another. A very excellent daily practice is to flex the body forward and as far as possible backward, a number of times while in the standing position. This has the effect of compressing the bowels and stimulating peristalsis, and is one of the most useful aids. It should be practiced once or twice a day: if once, in the morning on rising; if twice, at bedtime also. Rising to a sitting posture while lying on the back with the feet fixed is another exercise helpful in the correction of constipation; so is twisting of the body while standing. Daily exercise, including horseback riding, golf, and tennis, has an important influence in correcting constipation. I have known dancing also to be serviceable. The free use of plain water is sometimes sufficient to overcome the milder cases. Thus, a glass of water may be taken before breakfast and another at bedtime.

Last of all should aperients be employed. Unfortunately, these are often necessary. The simplest and least irritating should be employed. A simple tonic pill composed of 1-3 to 1-2 grain (0.022 to 0.033 gm.) of the extract of nuxvomica and 1-12 to 1-8 grain (0.005 to 0.008 gm.) of the extract of belladonna, three times a day, and kept up for some time in connection with the dietetic measures alluded to, is often sufficient.

But of actual aperients, the natural mineral waters are deserving favorites, especially Friedrichshalle, Apenta, Hunyadi János, and Carlsbad, and, when less active waters are required, the American Saratoga waters. The Saratoga waters are saline waters which present quite a range of proportion in their constituents, chiefly sodium chlorid, at the various springs. The waters of the Bedford Springs, of Bedford, Pa., are also very efficient, stimulating, as does the Saratoga water, the secretion of bile. The doses of all of these waters vary so much with circumstances that it is impossible to indicate them with definiteness. The minimum dose of the foreign aperient waters mentioned is two fluid ounces (60 c. c.), increased to eight fluid ounces (240 c. c.). Less than the latter quantity of the American waters is seldom used at a dose.

Of drugs, cascara sagrada has become deservedly popular. The best preparation is the fluid extract, as its dose can be readily regulated. From 10 to 30 minims (0.6 to 2 c. c.) may be given after the evening meal, and if this should prove insufficient, the same dose after the midday meal is to be

preferred before increasing the evening dose. The solid extract is, however, also efficient, and a grain or two (0.066 to 0.13 gm.) more may be added to the laxative pill already mentioned, or, if a more active aperient is desired, as many grains of extract of colocynth may be substituted.

An old favorite, a pill composed of extracts of aloes, nux vomica, and belladonna, in varying proportions, to be taken at bedtime, has been largely substituted of late by another made by the manufacturers and pharmacists, of aloin 1-5 grain (0.013 gm.), strychnin 1-60 grain (0.0011 gm.), and belladonna 1-8 grain (0.008 gm.), of which one or two are a dose. To such a pill podophyllin, in doses of 1-4 to 1-2 grain (0.0165 to 0.033 gm.), may be added with advantage, or blue mass in doses of 1-2 grain to 2 grains (0.033 to 0.132 gm.), or rhubarb one to two grains (0.066 to 0.013). The belladonna may be substituted by the extract of hyoscyamus, of which one to two grains (0.066 to 0.132 gm.) may be given. The compound licorice powder in which senna and sulphur are the active ingredients is a favorite aperient with some, but is bulky, and has a tendency to cause griping. The dose is a dram (3.8 gm.) or more.

A glycerin suppository or 1-2 dram (2 c. c.) of glycerin injected has become a favorite means of securing an evacuation. It should be remembered as a possible remedy, but it acts by irritating the lower bowel and soon loses its effect. The enema of plain water, one to two pints (500 to 1000 c. c.), though less convenient, is to be preferred, and some persons use it regularly. None of these measures is curative. They simply empty the bowel at the time, and systematic effort should be made to reduce them gradually, while the hygienic treatment is kept up.

Among the more unusual remedies recommended for chronic constipation is creasote, one drop daily, increasing one drop a day until the result is obtained.

It sometimes happens that an impacted fecal mass becomes channeled, and fecal matter may descend from above through it, and thus lead to the belief that normal passages are being secured. The physician should not be slow to explore the rectum with the finger, and by means of it or the handle of a spoon clear out the mass. This is often absolutely necessary before an evacuation can be secured.

Treatment of the Constipation of Infants.—I prefer to overcome this, when possible, by simple small enemas repeated until an effect is produced, and carried out at a fixed hour each day, preferably in the evening. The child is best held on the mother's lap, properly protected by a mackintosh and a small quantity, say two ounces (60 c. c.), of tepid water is thrown into the rectum. If it returns unchanged, after a few minutes' delay another syringeful is thrown in, and if necessary, another. Ultimately, a fecal discharge is usually thus obtained. I lay stress also on the regularity of this performance. It may be necessary to add a little soap to the hot water. Sometimes slight titillation of the anus by twisted pieces of paper answers every purpose. At the same time, the belly of the child should be massaged by the mother. Small suppositories of soap or of glycerin may be used if the measures mentioned are inefficient. For simple constipation in infants it is preferable to administer nothing by the mouth if it can be dispensed with.

Dilatation of the Colon.—This is one of the consequences of chronic constipation, though it may also occur as an acute condition, the result of

sudden obstruction, as by a twist in the meso-colon. It may involve the whole colon, but the vicinity of the sigmoid flexure is its usual seat. Two classes of cases of idiopathic dilatation are met,—first, that of adult males, generally over fifty years of age; second, that of children in whom abdominal symptoms have been present more or less since birth. In the former it is

Fig. 34.—Giant Congenital Dilatation of Human Colon.

The more distended end is the sigmoid flexure. The narrow part taking exit from it is part of the rectum, which was normal. The narrow distal end of the preparation represents the head of the colon with the string attached to a fragment of the small intestines. The arched part of the specimen represents a normal human colon photographed simultaneously for comparison of dimensions. Both were dried preparations.

thought that the overloaded sigmoid dependent into the pelvis and bent on itself becomes occluded and responsible for dilatation. The form met in chil-

dren is usually congenital and involves the lower portion of the colon, which is also hypertrophied. The congenital form becomes the direct cause of chronic constipation or coprostasis, which in turn increases the dilatation. Such is a remarkable specimen in the museum of the University of Pennsylvania, secured by the late Henry F. Formad* in the course of his work as coroner's physician. Two and a half pailfuls of feces, weighing 40 pounds (20 kilograms), were removed at autopsy.

Symptoms.—They are the same as those of obstinate constipation extending over weeks, in addition to enormous *distention* and *tympany* of the abdomen. Physical examination in extreme cases recognizes dislocation of the adjacent abdominal and thoracic viscera, especially the liver, spleen, heart, and lungs.

Treatment.—The treatment is that of the resulting constipation, which, in cases of this kind, is by enemas carried high up into the bowel, together with remedies which stimulate secretion into the upper bowel, of which calomel is one of the best. It should be given in doses of not less than 1-4 grain (0.016 gm.) hourly, until an effect is produced in association with that of the enemas. Dilatation probably results, at times, from the gradual accumulation of fecal matter, while frequent small discharges are being obtained which do not clear out the bowel. Hence the rectum should unhesitatingly be explored by the finger in doubtful cases. Complete evacuation of the bowels is sometimes extremely difficult, but if the exact state of affairs is appreciated, perseverance will ultimately conquer. Operation with exsection of large portions of the bowel has been done with excellent results.

NERVOUS AFFECTIONS OF THE BOWEL.

The bowel, like the stomach, is subject to deranged nervous influence, which manifests itself in:

- I. Increased or diminished contractility of the muscular coat.
- II. Increased or diminished sensibility of the bowel.
- III. Increased or diminished secretory function.

I. *Derangements of Motion.*—These are manifested by diarrhea, by constipation, and by cramp.

1. *Increased motor activity* producing *nervous diarrhea* occurs in adults and children, the result of increased peristalsis due to pure nervous influence. It implies a hyperexcitability of the nerves regulating peristalsis, causing them to respond to stimuli to which they are otherwise indifferent, such stimuli including the simple mechanical and chemical irritation of the natural intestinal contents. Hence we find nervous diarrhea in nervous, hysterical, and neurasthenic persons. In these persons, too, psychical influences, such as fright, depression, and even joy, cause diarrhea. The attacks of diarrhea which occur in tabetic persons have a similar origin through central nervous influence. Still more does such an excitability of the nervous system respond to unnatural irritation, such as that of teething in infants, producing diarrhea, which may be quite independent of irritating food, though the latter may co-operate.

* "Transactions of the Pathological Society of Philadelphia," vol. xvi., 1891-93, p. 23. Dr. Formad gives in his paper a summary of other cases reported.

There is no morbid change, and the bowel movements are generally watery and without blood or mucus. They vary greatly in frequency,—from two to twenty or more daily,—occur suddenly, and disappear often as suddenly as they come. They may last for several days.

2. *Decreased motor activity* producing *constipation*, the result of altered nervous influence, is even more common than diarrhoea.

In this condition, strictly speaking, the muscular coat has lost its impressibility to stimuli ordinarily sufficient to excite the automatic actions which result in bowel movements, and peristalsis is at a standstill. Associated with such condition is often an atony of the muscular coat, which permits gaseous overdistention and tympany. It is scarcely possible to separate such phenomena from those of impaired nervous sensibility of the bowel, to the paragraphs on which the reader is referred.

3. *Nervous cramp*, or excessive contraction of the intestinal muscles, is so intimately associated with pain that it will be considered in connection with deranged sensibility.

II. *Derangements of Sensibility*.—I. *Enteralgia*.—Sensory neuroses of the bowel are mostly in the direction of increased irritation of sensory nerves derived from the splanchnics, which contain the sensory as well as the inhibitory and vasomotor nerves to the bowel. Such irritation implies increased irritability of these nerves or the presence of unusual irritants. The pain thus induced, unassociated with organic lesion, is known as enteralgia or neuralgia of the bowels.

Associated with exaggerated contraction of the muscular coat it is known as *colic*, though the terms enteralgia and colic are also interchangeably used. Characteristic of enteralgia are its suddenness of occurrence and, to a less degree, the suddenness of its cessation. It is often associated with crampy contraction of the abdominal walls, when the pain is augmented.

Etiology of Enteralgia.—Among the causes which excite pain are such foreign bodies as indigestible articles of food, intestinal worms, fecal masses, overdistention with gases, and the like. The effect of the latter is attested by the relief which attends the discharge of gas. The operation of reflex causes must also be admitted. Such may be the mode of action of cold and of lead intoxication, which produces the well-known lead colic. Such is, possibly, gouty enteralgia, or the enteralgia succeeding an attack of gout. The enteralgia associated with certain nervous diseases, such as occurs in the painful enteric crises of locomotor ataxia, is probably the direct result of alteration in the sensitive nerves themselves. It may be, too, that the action of lead in producing lead colic is thus direct. The hysterical and hypochondriacal and the anemic are subject to colic through increased sensitiveness of nerves.

Diagnosis.—The pain existing in enteralgia is diffuse and throughout the abdomen. Enteralgia is to be distinguished from *enteric pain due to organic disease*. Most important are the inflammatory and ulcerative states associated with enteritis, typhoid fever, peritonitis, appendicitis, and intestinal obstruction. The diagnosis is usually not difficult. There is, first of all, the absence of fever; second, the history of the ingestion of irritating foods, or some one of the causes named. Very important is the point that colicky pain is relieved by pressure, while pressure increases pain in all of the affections named. Most difficult becomes the diagnosis in those cases in which there is coincident flatulence, as is sometimes the case in typhoid fever, when the question to be answered is, Is this colic, or is it the tenderness which comes

of peritonitis? Undoubtedly in some instances both are present, and one condition reacts upon the other.

The diagnosis from *appendicitis* has been considered in treating of the latter. *Intestinal obstruction* offers further similarity in the absence of fever, but the severity of the symptoms in obstruction is on the whole greater, their duration is longer, while constipation and vomiting are superadded. *Rheumatism* of the abdominal muscles sometimes resembles enteralgia very closely. In this, however, there is commonly exquisite tenderness, while the pain is superficial and more continuous. Nervous *dermalgia*, or hyperesthesia of the abdominal wall, has similar features and is common in hysterical women. Sometimes this is associated with hysterical colic, but even here, while the skin itself is sensitive, deep-seated pressure does not bring out increased pain.

Biliary colic and *nephritic colic* also resemble enteralgia, and may at first be mistaken for it, but careful examination should soon discover the points peculiar to each, such as localized tenderness and jaundice in the former and the course of the pain into the groin and testicle and thigh in the latter. *Uterine colic* may also be confounded, but the pain is distinctly localized in the region of the uterus and is apt to be associated with menstruation or to precede it.

It is important, also, if possible, to discover the form of enteralgia or its special cause, whether due to indigestion, to reflex causes, to constipation, to lead, to hysteria, or to central nervous causes. This is to be arrived at by close attention to the history and associated symptoms.

2. *Neuralgia of the Rectum*.—Some special symptoms characterize the sensory neuroses of the rectum which demand separate allusion. The nerves of the hemorrhoidal plexus are thus concerned. An uncomfortable aching sensation in the lower bowel and lower abdomen, extending at times to the sacrum, perineum, and genitalia, is the principal symptom. With this is associated an irresistible desire to go to stool, which is, however, fruitless.

As a reflex sensory neurosis of the rectal nerves may be considered a peculiar sensation of exhaustion and disposition to faint after a movement of the bowels, complained of by some persons. Wilhelm v. Leube also calls attention to an "intestinal vertigo," excited during the passage of feces through the anus, and capable of being excited, too, by introducing the finger into the rectum.

The sensory neuroses of the rectum are more common in nervous women and in the subjects of hemorrhoids, while tabetic patients are apt to suffer from the same symptoms.

3. *Diminished Sensibility*.—This is manifested for the most part only in delayed peristalsis. It has been said that constipation is one of its most constant results. In the case of the rectum, it is well known how, in health, we are informed of a desire to go to stool. Paralysis of these nerves results in anesthesia, which is followed by the absence of this desire. The effect must be an accumulation of feces in the rectum, which may still be evacuated if volition and the motor nerve route are intact, but which demands artificial removal if these are in abeyance. It is a constant symptom in those affections of the spinal cord associated with paralysis. To higher degrees is added the loss of the limited reflex control, and if there be also loss of the voluntary control over the sphincter ani, an involuntary stillicidium of liquid contents of the bowel results, though the solids go on accumulating unless

artificially removed. Thus is explained the constipation of the hysterical and neurasthenic.

The constipation associated with the passive congestion of heart and liver disease is the result of a similar lethargy of the nerves distributed to the muscular coat of the bowel. Here, too, we may infer an exhaustion of nervous excitability by overstimulation, if, as is suggested, normal peristalsis is excited by the stimulus of the carbonic acid of the venous blood, as well as by the food present in the intestinal tube. On the other hand, a food may be too-bland and unirritating to excite the normal peristalsis. Hence it is that constipation attends the use of milk and the farinacea.

The effect of paralysis of the voluntary muscles controlling the external *sphincter ani* results in inability to retain the fecal contents, whence involuntary evacuations take place, a frequent symptom in disease of the brain. Under such circumstances the control of the bowels is given over altogether to the reflex nervous center in the spinal cord, and man is reduced to the condition of the infant and the lower animals, in which defecation is a purely reflex act. Oversensitiveness or overstimulation of the sphincter would result in a spasmodic and painful contraction, which is, however, a very rare and anomalous condition.

III. *Secretion Neuroses*.—It is difficult to separate the consideration of the *secretion neuroses* of the bowel from that of the sensory and motor neuroses. Yet it is well known that secretion into the bowel may be influenced quite independently of peristaltic motion, perhaps through the vaso-motor nerves. Thus, while it is more than likely that the saline aperients produce their effect in response to the physical laws of osmosis, the secretion into the bowel which follows the hypodermic injection of pilocarpin cannot be explained upon any other ground than that of vasomotor nervous influence. Mention has already been made of the responsibility of the nervous system in producing the mucous discharges and casts referred to in discussing chronic enteritis.

Treatment of Neuroses of the Bowel.—This follows easily upon a correct diagnosis, which is indispensable. The primary point of attack is that of the nervous condition at fault. The removal of the causes of irritation should be coincident with measures directed to the relief of pain. If irritating ingesta are present, an emetic should be given. In children the gums should often be examined, and lanced when swollen and tender. If there is constipation, the bowels should be opened. If there is hysteria, a nervous sedative is indicated. In enteralgia the promptest means of relief is a hypodermic injection of morphin of 1-4 grain (0.0165 gm.) to an adult. Less may suffice, but if the pain is extreme, it is not worth while to temporize with smaller doses. On the other hand, it is not safe to give more at a single injection. Should this dose be ineffectual, associated with the local measures to be described, it may be repeated in half an hour. The combination of atropin 1-150 grain (0.00044 gm.), with the morphin will increase its efficiency.

Of local measures, massage is probably the most efficient for constipation and enteralgia. It has been mentioned that relief of the pain by pressure is characteristic of enteralgia. Especially happy results may, therefore, be expected from massage, an expectation that is realized in practice. Counterirritation to the abdomen by mustard or turpentine stupes may be used as an adjuvant to treatment in lieu of massage.

In milder forms of enteralgia, aromatics and carminatives, alone or in

combination with morphin, have always had a justified reputation. Some of these have been mentioned in considering the treatment of cholera and cholera morbus. An especially elegant and efficient preparation is:

℞ Spiritus ammon, aromat. }
 Tinct. card. comp. } aa ʒij (8 c.c.)
 Spiritus chloroformi }
 Spiritus vin. gall. }
 M. et. Sig.—Teaspoonful every half hour or fifteen minutes,
 in cracked ice or hot water until relieved.

Its efficiency is increased by adding a few drops of deodorized tincture of opium to each dose.

CARCINOMA OF THE BOWEL.

All parts of the bowel are subject to carcinoma, which occurs in growing frequency as the gut is descended. Thus, of all cases of bowel cancer, barely 5 per cent. are found in the small intestine, 15 per cent. in the cecum and colon, while 80 per cent. are met in the rectum.

In the small intestine, in the neighborhood of the orifice of the bile-duct, we meet most frequently the cylinder-celled epithelioma or adeno-carcinoma.

In the *large intestine* there is:

1. Cylinder-celled epithelioma, the most common form of cancer, in the cecum and sigmoid flexure.

2. Colloid cancer

3. Scirrhus

4. Soft cancer

5. Squamous epithelioma just above the anus

6. Sarcoma, including the melanotic variety

} in the rectum.

Benign tumors of the bowel, which may present symptoms similar to those of malignant tumors or no symptoms at all, include mucous polypi and fibromata, more rarely lipoma, myoma, angioma, and lymphoma.

Symptoms.—There are no symptoms distinctive of cancer of the bowel. The most constant local effect is more or less obstruction of the bowel, and we have already seen in our study of obstruction how far it is contributed to by cancer. There are, however, other symptoms which, added to those of obstruction, aid in the diagnosis. Particularly is this true in the case of the rectum.

The symptoms of obstruction met with in cancer of the bowel, already considered in treating of obstruction, include, especially, *constipation*, *pain*, *tumor*, *anorexia*, *nausea*, and, more rarely, *vomiting*. The added symptoms are *cachexia* and *altered fecal discharges*, which may include pus, blood, and, in few instances, fragments of cancerous tissue. Of the symptoms of obstruction named *tumor* alone demands further consideration, being the most important of all the symptoms of cancer. In fact, without it a certain diagnosis is scarcely possible. On the other hand, given a case of obstruction, the presence of tumor points more to cancer than to any other cause except intussusception and fecal impaction. As contrasted with intussusception, the tumor of cancer is of long duration and found in adults; as with impaction, it is tender and movable, usually harder and more irregular.

While the tumor may give a dull note to light percussion, to a hard stroke it is tympanitic. It may pulsate also if it lie over one of the large blood-vessels. Fecal tumors never do this. The difficulty of distinguishing from a fecal tumor is increased when a fecal mass is added to the cancerous tumor, but some of it may be cleared up by the use of purgatives and injections.

Cachexia, added to other signs of chronic obstruction, points to cancer. *Change in the shape of the formed feces*, especially a band-like flattening, is much spoken of. It may be produced by any cause which protrudes into the lumen of the large bowel, characterizes rather disease of the lower part, and, to be of value in diagnosis, it must be constant. The more or less constant presence of sanious pus, particularly of fetid character, is important evidence in favor of cancer.

Diagnosis.—Carcinoma of the duodenum is not easily distinguished from *tumor of the pylorus*; indeed, it is sometimes impossible to separate them. Both are movable tumors. With pyloric tumor are associated symptoms of obstruction and dilatation of the stomach. More rarely cancer of the duodenum has the same effect. The presence of jaundice points to cancer of the duodenum, as does also the continued natural acidity of the gastric contents removed after a test-meal, but neither of these symptoms is pathognomonic of duodenal cancer. In cancer of the stomach dyspeptic symptoms occur earlier and are more serious. Carcinoma of the duodenum may terminate suddenly by fatal hemorrhage. *Cancer* of the head of the *pancreas* also produces jaundice, but the tumor arising from it is fixed and immovable, and much more deep-seated than tumors of any portion of the bowel, being behind the pylorus and the transverse colon, between the left sternal border and parasternal line.

With the other abdominal tumors intestinal cancer is not likely to be confounded. The *floating kidney* is movable, but when sufficiently so to be compared in this respect with a cancerous tumor, is more movable, and may be generally returned to its natural seat. The kidney shape may not infrequently be recognized. Compression of the kidney often produces a peculiar sickening pain. The presence of nervous symptoms is especially characteristic of floating kidney, but there is no cachexia. A *movable spleen* is even less likely to be confounded, for similar reasons. It is, moreover, less sensitive. A *laced-off lobe of the liver*, often quite movable, can generally be traced to its normal attachment.

An actual *tumor of the kidney*, being behind the peritoneum, pushes the bowel and the ascending or descending colon before it, and must attain considerable size before it shows itself to the usual examination from the front. Such tumor very rarely compresses the bowel so as to produce symptoms of obstruction. The same may be said of tumors of postperitoneal lymphatic glands. An *ovarian tumor* is characterized by its deep-seated origin, its ascending development, and its relation to the uterus, as determined by joint vaginal and abdominal examination.

A *circumscribed peritoneal exudate* might be mistaken for a cancer of the bowel, but the history of its development, its flat percussion note, and the presence of some temperature, which characterizes it, are wanting in cancer of the bowel.

Cancer of the bowel is not likely to be mistaken for *appendicitis*, the acuteness of symptoms marking the grave form of the latter, while the absence of serious constitutional and cachectic symptoms is characteristic of the more chronic form of appendicitis.

Chronic inflammatory thickening of the bowel may, however, be a serious stumbling-block. Especially apt to occur about the sigmoid flexure, it produces also obstructive symptoms, and careful and prolonged study may be necessary to the making of a correct diagnosis. Cachexia remains absent in simple inflammatory stenosis for a longer time at least than cancer.

Diagnosis of the Part of Bowel Involved.—As to the part of the bowel involved, once assured that the tumor is of the bowel, some indication of its more exact location may be obtained by noting its position, which, if in the right abdominal region, suggests the duodenum; in the vicinity of the umbilicus, the transverse colon; in the right iliac fossa, the cecum, and in the left, the sigmoid flexure. It should be remembered, however, that serious dislocation of the tumor from its natural site may occur as the result of inflammatory adhesions formed while the tumor is temporarily in a position remote from its natural site. Often, too, a cancer of the sigmoid flexure gives no indication of its presence to abdominal examination. Distention of the bowel with water or gas and the application of the principles laid down from this standpoint, when treating of obstruction, may be availed of in settling this question (see p. 418). Allusion has been made to the presence of jaundice as characteristic of duodenal cancer; also to the retained natural acidity of the gastric contents removed after a test-meal as compared with gastric cancer.

Cancer of the rectum exhibits a somewhat special train of symptoms. The rectum is subject to the same forms of cancer as the pylorus, and in somewhat the same order of frequency, the columnar-celled epithelioma being most common.

The early symptoms of cancer of the rectum are those of *irritation*, including *pain*, *tenesmus*, the *discharge of mucus and blood*, and, probably, most cases of carcinoma of the rectum are mistaken at first for dysentery. In the cases of colloid cancer, the colloid material may be discharged from the bowel and reasonably mistaken for mucus. Fortunate is the clinician if it occurs to him to make an early examination of the rectum by the finger; for generally the disease can be felt, either as an ulcerated mass infiltrating the wall of the bowel, thus intruding upon the lumen, or as one or more nodular growths under the mucous membrane and adherent to it. If ulceration has occurred, bloody and mucoid matter, characterized by extreme and persistent fetor, is apt to adhere to the finger. Von Leube especially calls attention to hemorrhoids as a symptom of cancer of the rectum, and says they are seldom absent, because of the resistance opposed to the return of the venous blood. He claims he has discovered rectal cancer in examination suggested by hemorrhoids when no other symptoms were present. So, too, the presence of secondary cancer of the liver should suggest examination of the rectum, since marked instances of the former have been found associated with cancer of the rectum, otherwise latent.

Almost all morbid growths affecting the rectum are cancerous. Polypi, mucous and fibromatous, occasionally found in children, produce dysenteric symptoms, including bloody discharges, while they may project from the rectum during stool. Lipomata and other histioid tumors have been found at autopsy without having caused symptoms.

Prognosis and Treatment of Cancer of the Bowel.—The prognosis of cancer of the bowel is always unfavorable. Occasionally operative procedures have prolonged the life of the patient at the expense of an artificial anus in the lumbar or abdominal region, while resection has even been made

with some degree of success. Especially happy have been the results in some cases of exsection of the rectum.

The propriety of operation should, therefore, always be considered. Should it be decided against, the patient must be nourished by easily assimilable foods, such as peptonoids and peptonized milk, by the mouth or bowel, as circumstances may determine. A regular and sufficient evacuation of the bowels should be carefully looked after, lest impaction add its inconveniences to the others present.

HEMORRHOIDS.

SYNONYM.—*Piles.*

This troublesome affection lies on the border-line between medicine and surgery, and is, therefore, as appropriately considered from the standpoint of the physician as from that of the surgeon.

Definition.—A hemorrhoid is a mass of varicose or dilated and sacculated veins at the anus and lower rectum, the central situation being almost always the muco-cutaneous surface which joins these two structures. From this edge one or more piles may protrude externally or internally, constituting *external* or *internal* piles, the former protruding outside the gut, the latter within the sphincter.

Piles are called “open” or “bleeding” as they give rise to hemorrhage, and “blind” when they do not bleed.

Morbid Anatomy.—The external pile constitutes a little circumscribed tumor. Commonly there is more than one of these, whence the common use of the plural, “piles,” or “hemorrhoids.” They may be so numerous as to form a more or less complete circle around the anus. Within the sphincter the individual or tumor-like shape is more usually maintained, and the pile may be more elongated. The color varies from dark red to purple, the surface is smooth or lobulated, and the consistence is variously soft, hard, or elastic, corresponding to the degree of vascular turgescence.

On section the pile is found to be a mass of loculi filled with blood and separated by areolar tissue. These cells are produced by the sacculated and dilated veins referred to. After lasting for some time the structure becomes altered. The walls of the veins are thickened, the intervening connective tissue becomes firmer, and the whole pile grows harder, and appears more or less shriveled.

Etiology.—Piles are favored by the anatomical structure and relations of the seat at which they occur, more particularly the arrangement of the so-called hemorrhoidal plexus of the lower rectum. In health the plexus forms a rich, tortuous network lying between the muscular layer and the muco-cutaneous surface, and is subject to pressure by masses of fecal matter accumulated in the rectum and by straining at stool. The blood from the hemorrhoidal veins is discharged partly into the portal system and partly into the general venous system: the former through the superior hemorrhoidal and the inferior mesenteric veins, and the latter by the middle hemorrhoidal and the internal iliac veins. The plexus is therefore between the portal and general venous systems, but more closely connected with the

former. Hence obstructions to either the portal circulation or cardiac circulation, however induced, tend to engorge these veins, and become a predisposing or even sufficient cause of piles.

After the predisposing causes described, the most common cause of hemorrhoids is constipation and the accumulation of large quantities of fecal matter in the rectum. Hence it is that persons whose bowels do not act daily are very apt to be troubled with piles, and as women suffer much in this way, it is they who are most frequently victims. On the other hand, women suffer less than they would but for the relief afforded to congestions in this neighborhood by their monthly flow, so that it is not until after the menopause that they become most liable. Hence it is that hemorrhoids are more common in men up to the age of from forty-five to fifty, and that after this age more cases occur among women. The diseases in the abdominal cavity peculiar to women often produce hemorrhoids through the pressure they exert on, and the resistance they present to, the return of the blood from the hemorrhoidal plexus. Such are uterine enlargements and fibroid tumors of the uterus, ovarian tumors—in a word, any morbid growths which may invade the pelvic organs and become large enough to exert pressure. The pregnant uterus is another frequent cause of hemorrhoids in women, and thus hemorrhoids sometimes become one of the most distressing complications of the puerperal state.

Symptoms.—*External Hemorrhoids.*—The first evidence usually afforded of the presence of a hemorrhoid is a tender, painful lump, about as large as a pea, which makes its appearance just outside the *sphincter ani*, sometimes quite suddenly, more frequently requiring two or three days to attain its full development. This little tumor may pass away in the course of two or three days without treatment, or it may grow to larger size. If it disappears, it may never reappear, but more frequently it recurs—it may be not for months. In other cases the recurrence becomes more frequent, the condition lasts longer, and the inconvenience is correspondingly greater, especially during and succeeding defecation. The size of these tumors also varies, although they begin generally as described. The tendency is to enlargement with each recurrence, until they form a mass which more or less fills the anal region. The degree of hardness and pain also varies. Often the pain is excruciating and throbbing, and the patient will frequently compare the condition to that of a boil. In such cases it is impossible to sit because of the pain, and defecation is torture. If partially relieved, the swelling may diminish, and with it the pain and tenderness, leaving a fleshy mass smaller than the original pile, which may be permanent unless removed by operation. This fleshy mass may at any time become engorged again into a painful swelling, with the characteristics already described. More rarely, instead of the shriveling, suppuration may take place, and the pile is thus cured after weeks of suffering; or the circulation may be so interfered with that the hemorrhoid becomes sphacelated and ulcerates off.

In addition to the local symptoms named, there may be a sense of heat and fullness and itching about the anus. Occasionally, hemorrhoids bleed freely, affording relief to the suffering, and do no harm, if the bleeding is moderate. At times the bleeding recurs, constituting “bleeding piles.”

Internal Hemorrhoids.—When the pile is entirely within the sphincter ani, it is called “internal.” The sensation produced by piles in this situation varies also with their size, the rectum being sometimes quite filled with

them, causing a sense of fullness and an inclination to expel the mass, like that excited by the presence of feces in the rectum. Along with this there is often considerable secretion of mucus. The same anal sensations previously described as characteristic of external piles may be present, and, in addition, a dull, aching pain, extending beyond the anal region to that of the sacrum and sacro-iliac juncture. These hemorrhoids are also subject to bleeding, which will sometimes relieve them, and from them especially arise copious hemorrhages, producing at times great prostration.

Diagnosis.—The diagnosis of hemorrhoids is usually most easy. It is very common for the laity, however, to mistake a variety of conditions, including simple pruritus, eczema with and without pruritus, prolapsus ani, polypus of the rectum, condylomata about the anus, and even *fistulæ in ano*, for hemorrhoids, and absurd mistakes are sometimes made simply because the physician, from unfounded delicacy or other cause, does not make an ocular examination. The distinction from *prolapsus ani* may be briefly referred to. In prolapsus there is a smooth, symmetrical, complete annular protuberance, more prominent than hemorrhoids and, as a rule, less painful. It is also usually more easily reduced. The *polypus* is recognized by its pedunculated attachment, and the condyloma by its wart-like appearance and its light color as compared with the red of hemorrhoids.

Prognosis.—This is usually favorable, particularly if treatment be instituted early, and it is most frequently in consequence of neglect of treatment that the tumors go on from bad to worse, and that operation is ultimately required for their successful cure. Reference has been made to the free hemorrhage which sometimes occurs, even causing the patient to faint from loss of blood; yet, I never knew death to result.

Treatment.—Apart from the prophylaxis furnished by attention to the bowels, this is further secured by absolute cleanliness. Advantage should be taken of the daily bath to wash the anal region thoroughly with water and soap. All irritating particles are thus removed, and any tendency to hyperemia is kept subdued. The first condition necessary to successful treatment is to remove, if possible, the predisposing causes, as constituted by diseases of the heart or liver, or by pelvic tumors, including uterine enlargement, and to favor the return of the blood from these parts. Constipation being the immediate cause of the vast majority of cases of hemorrhoids, it should be corrected, and every effort should be made to secure free and easy movements of the bowels daily. Fortunately, the same treatment which relieves the constipation tends also to relieve the portal engorgement so often the cause of the hemorrhoids. Hence, mercurial purges are especially indicated, and among these blue mass is the best. It may be combined with compound extract of colocynth, from 2 to 5 grains (0.132 to 0.33 gm.) of each, with 1-4 grain (0.0165 gm.) of extract of belladonna, and may be given nightly in the smaller dose, and two or three times a week, if the larger, followed by a saline in the morning, until the acute stage is passed. Senna, sulphur, and cream of tartar or compound jalap powder have long been favorite remedies. They may be given in various combinations. An excellent aperient to be used in this way is equal parts of precipitated sulphur and bitartrate of potassium, made into an electuary with syrup, of which mixture two teaspoonfuls may be taken nightly. Another combination is powdered jalap and bitartrate of potassium, each half an ounce; confection of senna an ounce, made into an electuary with simple syrup or syrup of orange, of which half a teaspoonful may be given nightly or two or three times a day,

as found necessary. The natural aperient waters—Apenta water, Hunyadi water, Rubinat water, Carlsbad water, the Saratoga waters, and others of this class—may be substituted or added in the morning on an empty stomach.

After this the medicinal treatment consists largely in the application of astringent ointments, of which equal parts of ointment of galls and ointment of belladonna, the favorite. Simultaneously with the application of this the pile should be patiently reduced and returned within the sphincter, the ointment being used in the manipulation, as well as subsequently applied and properly retained by dressing. In certain cases in which the inflammation is very decided nothing can be accomplished until cold applications, such as ice-water or ice itself, are made to the part and retained there. Satisfactory results from this treatment are greatly favored by the patient going to bed; indeed, it is scarcely possible to carry it out otherwise, and some such treatment as this is sometimes necessary to force the patient to bed. The application of cold is often efficiently made by a stream of water played upon the part for fifteen minutes or more, using a bidet or rubber hose attachment to a spigot. If the inflammation has been reduced and the astringent ointment is insufficient, I have frequently obtained good results by applications of Monsel's solution of persulphate of iron, applied with a brush, once or twice daily. By this means, used conjointly with the astringent ointment, I have seen large and painful hemorrhoids dwindle away in the course of a few days. In all instances where these applications are made to external hemorrhoids suitable measures should be used to protect the linen from soiling. Too much stress cannot be laid upon the return of the hemorrhoid within the anus and pressing or "seaming" it down with the finger each time it comes out.

D. W. Saniways recommends the application of collodion to external hemorrhoids. The hardening of the collodion supports the pile and stimulates it to contraction. It is directed to be dropped on a few fibers of cotton wool which are spread over the pile each morning after defecation.

The medical treatment of *internal hemorrhoids* is not essentially different from that for external hemorrhoids. The suffering in this form is not usually so great, though hemorrhage appears to be more frequent from this kind of pile than from the external form.

Failing by the above described efforts to cure, recourse must be had to operation, which will carry us into the field of surgery, to the text-books on which the reader is referred for suitable operative methods.

DISEASES OF THE LIVER.

ABNORMALITIES IN THE SHAPE AND POSITION OF THE LIVER.

Altered Shape.—The only abnormality in the shape of the liver requiring special mention is the “laced-off” or “corset” liver. In this the right lobe is divided by a transverse furrow, more or less deep, into two nearly equal parts. In extreme cases the connecting furrow is a mere fibrous band, and the liver can be folded on itself; in others it contains more or less liver parenchyma. It is usually caused by the pressure of a tight waist-band or corset, and accordingly is more frequent in women, but it is met also in men.

It seldom gives rise to any symptoms, but sometimes leads to confusion in diagnosis, being especially frequently mistaken for a movable kidney or an abdominal tumor, for the inferior portion may extend as low as the crest of the ilium. This confusion is increased if, as occasionally happens, a loop of intestine lies in the furrow and gives a tympanitic note on percussion; whence the inference that the lower portion is a separate organ. Skillful palpation is a valuable means for determining the true nature of such a condition. The edge of the liver should be followed around from the epigastrium into the right lumbar and iliac regions. If the continuity with the supposed tumor is uninterrupted, the latter must be a portion of liver laced off. It is not unlikely that such a condition may occasion symptoms of dragging and weight, with the nervous strain frequently incident to them, like that which is so characteristic of floating kidney. The corset-liver is said to be one of the favoring causes of cholelithiasis, by reason of its interference with the natural onward movement of the bile.

Abnormality of Position.—The liver in cases of transposed viscera is found on the left side. More frequently it is simply turned downward or upward, anteverted or retroverted as it may be on its transverse axis, chiefly as a consequence of tight lacing in women. It may be pushed upward above its normal site by ascitic fluid or abdominal tumors, and downward by pleuritic effusion on the right side or by emphysema of the right lung.

The *floating liver* is by far the most interesting of these conditions. When it occurs, the natural site of the liver is vacant, especially when the patient is in the upright position, occupied usually by hollow viscera, or, in rare instances, by morbid growths. The condition of such movableness is a long suspensory ligament and a coronary ligament so stretched as to form a sort of mesohepar, which permits the liver to fall out of its normal position. It occurs usually in women past middle life, with loose abdominal walls, and is favored by tight lacing. It has been met with in men. It is sometimes responsible for the condition known as the pendent belly. It is a rare condition.

The organ itself is usually easily recognized as a large, hard, but movable tumor, below its normal place, and having also the shape and size of the liver, while the normal site is tympanitic on percussion or occupied by organs which do not give the same outline on percussion. The suspensory ligament may also be felt. The organ may generally be restored to its normal position when the patient is recumbent.

The same dragging symptoms mentioned as characteristic of the con-

stricted liver, with the usual contingent of nervous symptoms which succeed upon it and the movable kidney, may be present here.

Treatment.—The treatment for both of these conditions—the constricted and the displaced liver—must consist in some instrumental means by which the organ or constricted portion can be held in position.

Diseases of the Bile Passages and Gall-bladder.

JAUNDICE OR ICTERUS.

Definition.—Jaundice is not a disease, but a symptom, consisting in a yellowish discoloration of the skin and other tissues by coloring-matters derived, in some cases, directly from the bile, and in others directly from the blood. The shades of coloring range from a very pale, scarcely appreciable, yellow to a brown olive hue. It is a symptom present in so many different diseases of the liver, and so associated with other symptoms more or less constant that its separate consideration is justified.

Etiology.—As intimated, its immediate cause is a deposit of pigment in the skin, which, in the majority of cases, is reabsorbed bile pigment. In other instances the pigment represents the coloring-matter from disintegrated red blood discs, disintegration so rapid that the liver, spleen, and kidneys, all combined, are unable to eliminate the hematin. It has also been claimed that jaundice may be due to suppressed secretion, the result of extensive destruction of liver cells, but this has been rendered very unlikely by the experiments of Stein, who found that jaundice did not occur when the entire blood supply of the pigeon's liver was cut off. The jaundice due to bile absorption has received the name *hepatogenous* jaundice, because of its purer hepatic origin; the second form is called *hematogenous*, because disintegrated blood is its direct source.

Reabsorption of bile takes place when there is obstruction to its onward movement, such as results, for example, from impaction of a gall-stone in the hepatic duct or common bile-duct; from closure of the duodenal end of the common bile-duct by inflamed and swollen intestinal mucous membrane; from complete or partial obliteration of the duct by adhesive inflammation; and from pressure from without by morbid growths. These growths may be enlarged glands in the fissure of the liver, or tumor in the gall-bladder, in the liver itself, in the pancreas, and in the stomach, and especially cancer of the pylorus and duodenum. More rarely tumors of the kidney or omentum, abdominal aneurysm of the celiac axis or aorta, or enlargement of the uterus may occasion obstruction. So may fecal accumulation. The morbid states in the liver which may produce jaundice are cancer, abscess, hydatid cysts, and cicatrices, all of which will be referred to again. It is reasonable to suppose that the bile is absorbed from the overdistended biliary vessels by the adjacent capillary vessels of either portal or hepatic vein system facilitated by pressure. Reduced pressure in the blood-vessels of the liver, as contrasted with that in the biliary vessels and ducts, also favors reabsorption of bile from the latter. Such explanation is speculative, but thus have been explained those interesting cases of jaundice brought about by emotion. Those who have read the charming story of "Put Yourself in His Place," by Charles Reade, will recall the case of Henry Little, whose attack of jaundice is described with the skill of an expert physician.

It should be mentioned, also, that the hematogenous form of jaundice has recently been denied by Stadelmann, who holds that all jaundice is hepatogenous in origin, and that the needed condition of obstruction is secured in the so-called hematogenous form by a plugging of the smaller bile-ducts by viscid bile or catarrhal secretion, or by compression of these ducts by swollen adjacent liver cells, or by leukocytic infiltration of the interstitial tissue. I do not as yet feel justified in discarding the heretofore accepted classification.

Associated Symptoms.—1. *Of Hepatogenous or Obstructive Jaundice.*—This is the usual form of jaundice. All ages are subject to it. In addition to the discoloration described there is often an annoying *itching of the skin*, due to irritation of the deposited bile pigment. Further evidence of the irritation thus caused is seen in occasional *eruptions*, such as urticaria, lichen, and even furuncles. A *bright yellow discoloration of the sclerotic coat of the eye* is as constant as the staining of the skin, while the mucous membranes are often similarly tinged.

After the skin, the *urine* exhibits the most conspicuous alteration, even in mild cases. Indeed, "bilious urine" is sometimes the first symptom. The color may be slightly yellow or deep brown, like that of porter. The presence of bile pigment in the urine is readily shown by Gmelin's nitric acid test, though ordinary nitric acid answers nearly as well. A few drops of the urine and half as many of the acid are placed on a porcelain plate and gradually allowed to approach and fuse, when a brilliant play of colors appears, in which green, yellow, red, and violet are most easily recognized. The reaction is due to the oxidation of the bilirubin by the acid. The demonstration of the biliary acids by Pettenkoffer's test with cane-sugar and sulphuric acid is impossible unless the bile acids be first separated by a tedious process. One of the most reliable ways of recognizing bile in the urine is by the stained cellular elements which it contains. Under no other circumstances are the bright yellow-stained cells found, and they are even met with when the quantity of coloring-matter is insufficient to react by Gmelin's test. In a few cases the bilirubin reaction is not obtainable, when the urine contains in increased amount its normal coloring-matters, urobilin or hydrobilirubin—*i. e.*, reduced bilirubin.

Of the *remaining secretions*, the perspiration is often stained, the milk rarely, the tears, saliva, and mucus not at all. There is sometimes a bitter taste in the mouth, showing an elimination of some constituent of the bile by the buccal glands, probably the salivary.

On the other hand, the *feces* are devoid of biliary coloring-matter, and their pale-gray or pipe-clay color has long been significant of the absence of bile. For the same reason the bowels are usually constipated and the discharges pasty, ill-smelling, and acid. Occasionally there is *diarrhea*, which may be caused by the irritating effect of the feces disposed to rapid decomposition, because of the absence of their natural antiseptic ingredient. For the same reason, too, the absorption of fats is hindered. There may be other signs of gastro-intestinal derangement, such as *loss of appetite*, *nausea*, *fetid breath*, and *fullness in the epigastrium* after eating. *Gastro-intestinal hemorrhages* have been noticed in grave cases. In cases of long standing there may be *albuminuria* as well, with bile-stained tube-casts.

Very characteristic of simple obstructive jaundice is a *slow pulse*, which may be as infrequent as 50, 40, or 30. It must be due to some stimulating

effect on the inhibitory action of the pneumogastric nerve. The breathing rate, on the other hand, is normal.

The chief subjective symptom of jaundice is *depression of spirits*, which may even amount to melancholia. *Irritability* is also prominent. *Headache and vertigo* are frequent. *Vision* is variously affected: to some, objects appear yellow; some see better by obscure light—nyctalopia; to others, the approach of darkness is associated with more than usually difficult vision—hemeralopia. Grave nervous symptoms, rarely manifested, are *sudden coma*, *acute delirium*, and *convulsions*. These usually supervene in cases of long standing, and are attended by *fever*, *rapid pulse*, and *dry tongue*—the symptoms, in a word, of the typhoid state. The term cholemia is applied to the sum of these symptoms, and the condition is regarded as due to the presence in the blood of the constituents of bile, of which cholesterin is the most important; whence also the name cholesteremia.

The *liver* is more or less altered, in accordance with the disease which may be present in it and responsible for the jaundice. These changes will be considered in treating of the diseases in which jaundice is a conspicuous symptom. It may also be bile-stained, as are other internal organs, especially the kidneys.

The *duration* of this form of jaundice depends upon the disease which is responsible for it, and it may be a few days or many months. In chronic cases remission and exacerbations occur, but the longer the duration, the more likely is there to be some organic change in the liver.

2. *Of Hematogenous Jaundice*.—The symptoms of this form are those of the diseases which are responsible for the hemolysis—viz., acute yellow atrophy, phosphorus-poisoning, yellow fever, bilious fever, typhoid, typhus, and relapsing fevers, pyemia, pernicious anemia, snake poison, chloroform, and other poisons. In all of these there is some toxic agent working destruction of the blood. It should be added that in this form of jaundice the *stools are not clay-colored*. The urine also is less bile-stained, though the true urinary pigments, notably urobilin, are often very much increased.

Diagnosis.—One of the most frequent errors of the inexperienced, and a constant one of the laity, is to mistake for jaundice a dirty, yellowish discoloration of the skin, known as sallowness, which is symptomatic of general ill health, especially of uterine disease in women and of malarial poisoning. It is probably an anemia, and may be distinguished from jaundice by the fact that it is not associated with staining of the conjunctiva and secretions. It is, moreover, not a yellow, but a dirty brown. One needs only to have his attention aroused to avoid error.

Much more closely does the discoloration of the skin in *Addison's disease* resemble that of some cases of jaundice. In the former there is no discoloration of the sclerotic coat nor of the urine, while the feces remain natural. In Addison's disease the exposed portion of the body and its flexures are more deeply stained.

The purpose of diagnosis includes the discovery of the cause and seat of obstruction. In the first place, most cases of acute jaundice are due to catarrhal inflammation of the common bile-duct. If associated with fever, it may be assumed that the smaller ducts are involved. After this, obstruction by gall-stones causes many cases; then follow hypertrophic cirrhosis and the various malignant diseases of the liver, hydatid disease, abscess, pressure by enlarged glands in the fissure of the liver, and others mentioned on page 436.

Prognosis.—This depends on the cause of producing it. Ordinary catarrhal jaundice invariably is recovered from in from two to six weeks, and jaundice from impacted calculus usually sooner or later. When due to other causes, its duration depends on them. In the hematogenous form the duration is brief, because the termination of the disease causing it is usually early and fatal.

Treatment.—The treatment of both forms of jaundice must be directed to the conditions causing it, and will be appropriately considered in discussing them.

ICTERUS NEONATORUM.

SYNONYM.—*Jaundice of the New-born.*

Jaundice occurs in new-born children in a simple and *harmless* form, with symptoms comparable to obstructive jaundice, and in a *grave* form comparable to hematogenous jaundice. The first is probably a form of obstructive jaundice due to like causes, though it has been assigned a hematogenous origin. It is much the more frequent, and disappears in from a few days to several weeks. The grave form is usually fatal.

A patulous ductus venosus has been suggested as an avenue through which the portal blood which contains bile enters the circulation.

The grave form has been found associated with absence of the hepatic duct or common duct, with congenital syphilitic hepatitis, and with septic phlebitis of the umbilical vein.

Treatment.—The simple form of jaundice of new-born infants demands no treatment. In the graver forms treatment is of no avail unless the condition be traceable to syphilis, when it demands the treatment of that disease in its tertiary form.

SIMPLE CATARRHAL JAUNDICE.

SYNONYMS.—*Duodeno-cholangitis; Inflammation of the Common Bile-duct.*

Definition.—The term catarrhal jaundice is applied to jaundice due to any inflammation of the common duct not the result of impacted gall-stone.

Etiology.—The most frequent cause of such inflammation is the extension of a gastro-duodenitis into the common duct. To the same cause is ascribed the jaundice sometimes occurring with passive congestion of the liver due to mitral valvular heart disease, also that found in association with the infectious diseases, especially pneumonia, or with mental emotion. Catarrhal jaundice may also be epidemic. The jaundice in hypertrophic cirrhosis is probably likewise due to cholangitis.

Morbid Anatomy.—Opportunities of studying postmortem conditions after catarrhal jaundice are not often afforded, but when they occur, the duodenal end of the duct—the *pars intestinalis*—has been mostly involved. In it the mucous membrane is swollen, while its orifice and the diverticulum of Vater may be filled with mucus. The inflammation may extend up into the cystic duct, and even higher, into the hepatic duct and branches. Suppuration does not take place in this form of cholangitis.

Symptoms.—Excepting the jaundice, there may be no symptoms. There is no pain, but there may be *tenderness*, due to gastro-intestinal derangement rather than to the hepatic state, though this may cause it, while such derangement may also lead to *general malaise, loss of appe-*

tite, coated tongue, fetid breath, nausea, vomiting, a sense of fullness, constipation, or irregular action of the bowels. There may also be slight *fever*, particularly if the smaller biliary passages are involved. If the gall-bladder is distended and can be felt at the edge of the liver, there is probably obstruction of the common duct, and if there are pain and tenderness, the obstructive agent is probably a gall-stone. The paler the feces, the more complete must be the obstruction, and the more likely is it to be in the common duct, for, with obstruction of the cystic duct, there may still be a discharge of bile into the intestine; also with obstruction of the hepatic duct until the gall-bladder is empty, which, however, soon happens. Obstruction of the hepatic duct is unassociated with distention of the gall-bladder, while there will be jaundice. Obstruction of the cystic duct may still be associated with distention of the gall-bladder, either through transudation or pus-formation, but there may be no jaundice, and the feces may remain colored. If the jaundice is chronic or permanent, we must look for some organic change in the liver or external permanent cause of obstruction outside of its condition. In the hematogenous form the jaundice is usually so plainly secondary to other symptoms that there is little difficulty in recognizing its cause.

Diagnosis.—The presence of jaundice without pain or other symptoms points almost invariably to catarrhal jaundice. The same diagnosis is justified by the presence of the symptoms of gastro-intestinal catarrh, of associated mitral disease, or of any of the infectious diseases.

Prognosis.—Unless associated with infectious diseases or with hypertrophic cirrhosis, the prognosis of catarrhal jaundice is favorable. In the diseases referred to the danger is not from the jaundice, but from the diseases with which it is associated.

Treatment.—The treatment of catarrhal jaundice resolves itself into two parts: first, that for the catarrhal state; second, that demanded by the absence of bile in the small intestine.

For the catarrhal inflammation, either of the duodenum adjacent to the duct or of the duct itself, local depletion is indicated. This is accomplished by the use of saline aperients and the natural mineral waters which act similarly—*i. e.*, produce watery stools. Of the former, Rochelle salts, Epsom salts, or the solution of the citrate of magnesium are representative; while the Saratoga, Hunyadi János, Friedrichshalle, or Rubinat and Carlsbad waters represent the latter. These should be taken daily in aperient doses. In this country the Saratoga mineral waters, particularly those of the Hathorn Spring, are especially valuable, and no better course can be pursued by those who can afford it than to spend some weeks at Saratoga. The Bedford Springs waters, near Bedford, Pa., are also useful, but not nearly so efficient as the Saratoga waters. Of foreign waters, those of Carlsbad are especially valuable, and in Europe these springs may be resorted to. Their use may also be associated between meals with that of the alkaline mineral waters, of which those of Vichy and Vals are the type. These waters are largely employed in this country, and may be availed of at home. There is no indication for the use of calomel, which is so often prescribed, as it is not reasonable to believe the secretion of the bile can be so stimulated by it as to force onward any obstruction, whether by calculus or swollen mucous membrane, until the latter is depleted. After the flow into the intestine is resumed, calomel may be given to stimulate it further. Podophyllin and colocynth may be used for the same purpose. Sodium salicylate has also a

reputation to this end. Irrigation of the large bowel with cold water has been recommended as a means of stimulating the descent of the stone.

The second indication should be met by the use of such food as does not require the bile to facilitate its digestion or absorption or to prevent its decomposition. Fats and oils should, therefore, be avoided; hence skimmed milk, animal broths, and egg-albumen, with an abundance of liquids, are indicated. The liquids may be some one or more of the mineral waters previously named, or, in their absence, plain water. Warm bathing is especially indicated, as it causes elimination by the skin and relieves the itching. Lotions of carbolic acid and glycerin are also useful to this end.

CHOLELITHIASIS.

SYNONYMS.—*Hepatic calculus; Biliary calculus.*

Etiology.—Since the great bulk of the gall-stone is cholesterin, an evident condition of its formation is a precipitation of this substance from the bile, of which it is the chief constituent. The thicker the bile, the more likely it is to throw down sediment. Moreover, recent studies, especially by Naunyn, have shown that micro-organisms play an important part in the production of gall-stones, primarily by exciting a catarrhal inflammation which modifies the chemical composition of the bile and favors the precipitation of cholesterin and of lime salts, in combination with epithelial débris and bacteria. The typhoid fever bacillus is an especially frequent cause of inflammation of the gall bladder. Naunyn also showed that cholesterin and lime salts are a secretion of the mucous membrane of the gall-bladder and bile-ducts, and that it is a function which is especially active when the mucosa is in a state of inflammation. If, as is supposed, the cholates of sodium hold cholesterin in solution, it is plain that their decomposition or destruction may cause precipitation, which may also be further favored by micro-organisms.

Occurrence.—Gall-stones have been met in infants and in the new-born, but practically are found in adults only, while their tendency to form appears to increase from the age of thirty upward. Most patients who consult us for the effects of gall-stones are over forty and under fifty. Cholelithiasis is also very much more frequent in women than in men; according to Naunyn, four times as frequent, and especially so in women who have borne children or have had abdominal tumors. He says that 90 per cent. of women who have gall-stones have borne children.

Naunyn says, too, that 25 per cent. of all women who die have calculi in the gall-bladder. Lack of exercise, sedentary habits, and tight lacing are held partly responsible for this, and with some reason, since all of these conditions are calculated to impede the movement of bile. Cholelithiasis has been found associated with the habit of free eating of starchy and saccharine foods and in stout persons; yet I recall striking cases among the lean also. The movable liver and the movable right kidney are likewise said to predispose to cholelithiasis. Constipation and a tendency to depression of spirits are apt to be associated, probably as effects rather than causes.

Morbid Anatomy.—The gall-stone itself is a brown object, nearly spherical, oval or faceted, and even polygonal in shape, usually the size of a pea, or as small as a millet-seed, producing in aggregation "gall sand." The faceted shape is produced by close packing of a large number of stones in a

gall-bladder, as frequently happens. More rarely the stone is irregular—mulberry-shaped. In addition to cholesterin, which makes up from 70 to 80 per cent. of most stones, they contain in various but still small amounts bile pigment, calcic carbonate, and organic matter. A few are made up almost entirely of bilirubin and lime. On section, the stone exhibits either a concentric or homogeneous appearance, with or without a nucleus of bile pigment or organic matter, and very rarely of some foreign body. The cholesterin

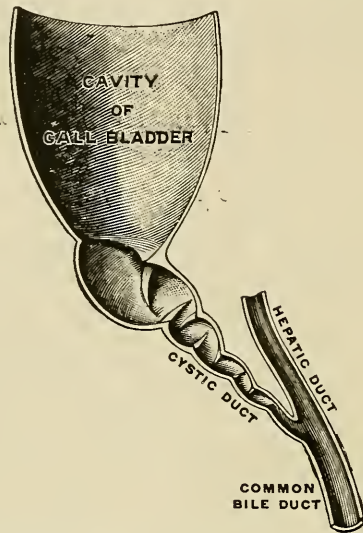

Fig. 35.—The Cystic Duct in Section, with Part of the Gall-bladder and Hepatic and Common Bile-duct.—(Testut).

stones are almost completely soluble in etherized alcohol, whence beautiful crystals of cholesterin may be obtained after evaporation.

In addition to their enormous accumulation in the gall-bladder, where they may be counted sometimes by hundreds, they are found anywhere in the biliary tract between the duodenal end of the common duct and the ultimate ramification of the bile vessels. Outside of the gall-bladder the cystic duct and the common duct are naturally the situations in which lodgment most frequently occurs. If in the common duct, it is usually at the orifice of the papilla in the diverticulum of Vater, and from the duodenal side the stone feels as though it were directly under the mucous membrane. Two or even more stones may be found in the duct. The common duct under these circumstances may attain a diameter of an inch (2.5 cm.) or more. Permanent obstruction of the cystic duct causes dilatation of the gall-bladder—*hydrops vesicæ felleæ*. Such dilatation may be enormous, filling the entire abdominal cavity, and has been mistaken for ovarian tumor; usually it is more moderate, but the contents frequently amount to a pint (500 c. c.) or more. The contents are a colorless, viscid, or watery fluid, more or less albuminous, and neutral or alkaline in reaction; the greater the dilatation, the more aqueous and unlike bile do its contents become. In any situation the stone may produce ulceration and even suppuration, with perforation into the peritoneal cavity or adjacent organs, the duodenum, stomach, transverse colon, right renal pelvis, ureter, through the diaphragm into a bronchus, and into the abdominal wall.

The various situations in which gall-stones are lodged may be easily learned from the accompanying Figure 35.

ACUTE IMPACTION.

SYNONYM.—*Biliary Colic*.

Symptoms.—The characteristic symptom of impacted gall-stones is *biliary colic*, but biliary colic is by no means always present in every case of cholelithiasis. The gall-bladder is often found full of calculi without the suggestion of a symptom. Small stones even pass into the duodenum without producing symptoms. Commonly, however, they lodge while in this transit, and give rise to attacks of *pain* which are known as biliary colic. This pain is usually sudden, very severe, often excruciating, and the patient writhes in agony and sometimes faints in consequence. It is usually referred to the epigastrium, whence it radiates in all directions over the abdomen and at times into the right shoulder and arm. As a rule, however, it is localized on the right side, under the liver. It is a sharp and cutting pain. There is always *tenderness* in this region, which varies in degree. It is sometimes associated with a more or less rigid state of the abdominal muscles of that side. The duration of the pain is that of the lodgment of the stone, and it may be from a few hours to weeks, ceasing rather suddenly when the stone is discharged into the bowel. There may, however, be remissions. *Nausea* and *vomiting* are almost invariable symptoms of biliary colic. They often bring temporary relief through the resulting relaxation. *Fever* is soon added to the pain, while a *chill* is not infrequent. The temperature is usually 102° F. to 103° F. (38.8° C. to 39.5° C.). It may be intermittent, but such intermission is more apt to be associated with prolonged obstruction, constituting with a chill a part of the symptoms of so-called *hepatic fever*, to be next considered. Gall-stone crepitus may sometimes be detected when the gall-bladder is packed with calculi.

If the attack last long enough, *jaundice* almost always supervenes, whence we infer, too, that the stone is likely to be in the common duct, having probably started in the cystic duct. Three or four days may elapse between the beginning of obstruction and the supervention of jaundice, the degree of which increases with the completeness and duration of obstruction. The entrance of the stone into the common duct may be attended by one of the remissions alluded to, though the jaundice grows even deeper on account of the more thorough obstruction to the descent of the bile.

The liver is sometimes slightly enlarged, as determined by percussion. A rare symptom is *collapse* with fatal syncope, due to perforation at the seat of lodgment, with consequent *peritonitis* and *shock*.

Diagnosis.—This is commonly easy. While the pain may be more or less diffuse, it is for the most part localized in the right lower thoracic and upper abdominal regions, and the tenderness is always there, while, if jaundice and biliary urine are present, all doubt is removed. *Nephritic colic* and biliary colic are confounded with surprising and unjustified frequency. In the former condition the pain starts in the lumbar region and radiates downward into the groin, the testicle, and the inside of the thigh. Such error is fortified by the fact that bilious urine is too often confounded with bloody urine. It should be necessary only to mention this to guard against error.

Cholelithiasis has been mistaken for acute pleurisy in the vicinity of the gall-bladder and the reverse mistake has been made. The friction rôle of

pleurisy should preclude an error, but the friction rôle may not be present at the particular stage.

Our growing knowledge of *appendicitis* has led to the discovery that the pain characteristic of this disease is sometimes localized in the right hypochondrium, where, indeed, the appendix has been found at operation. Jaundice and bile-stained urine do not, however, attend *appendicitis*. *Gastralgia* has been confounded with biliary colic, but attention to the symptoms described when treating that affection should prevent mistake. The term hepatic neuralgia has been applied to an apparently causeless pain, sometimes felt in the neighborhood of the liver, but it is less severe than biliary colic and unaccompanied by any of the other symptoms. This is allied to *pseudo-biliary colic* which is to be remembered as a possible event in nervous women. Both are characterized by the absence of jaundice.

It is very important, immediately after an attack of supposed biliary colic, to *search for a stone* in the fecal discharges. For this purpose the mass should be placed on a sieve, and water passed over it until all soluble parts are run out. Such examination should be kept up for several days after the attack, for the stone is not always passed immediately.

Prognosis.—The termination of an ordinary attack of biliary colic is, in the vast majority of instances, favorable. It is only in the rare cases, where perforation takes place, that a fatal ending follows. Surgery of the gall-bladder has come to be an important division of surgery, and many lives have been saved by operations before and after perforation. The surgeon should, therefore, be promptly sent for. More frequently the escape of the stone is long delayed, producing the symptoms of chronic impaction, to be next described.

CHRONIC IMPACTED GALL-STONE.

Symptoms.—These vary somewhat with the seat of the impaction and its duration. From this standpoint they may be divided into certain groups:

1. *Symptoms Due to Chronic Calculous Obstruction of the Cystic Duct.*—In addition to more or less of the symptoms detailed under acute impaction, the immediate result of such obstruction is dilatation of the gall-bladder, or *hydrops vesicæ felleæ*, already referred to. Contrary to what might be expected, dilatation is more frequently caused by obstruction of the cystic, than of the common duct. The source of the accumulation is not, however, the bile, which, as might be expected, cannot get into the gall-bladder through the obstructed duct any more than it can get out of it. It is the products of inflammation of the mucosa, added to the bile previously present, which cause the dilatation. The occasional enormous dilatation has more than once been mistaken for ovarian disease, an error the more excusable when we remember that *jaundice is often absent*. More frequently the dilatation is moderate, and can be felt below the edge of the liver as a round or ovoid elastic tumor, in which fluctuation may sometimes be obtained.

2. *Symptoms Due to Chronic Calculous Obstruction of the Common Duct.*—If the common duct is obstructed, dilatation of the gall-bladder does not necessarily follow, and if it does occur, the dilatation is moderate. Such obstruction is commonly associated with cholangitis, catarrhal or suppurative. (a) *In simple chronic catarrhal cholangitis* the common duct is dilated; at times also the branches of the hepatic duct extending into the liver. This condition has been especially studied by Charcot and Murchison abroad and William Osler in this country. It may be intermittent or remittent. Very

interesting among the causes of intermittent obstruction is the movable or ball-valve stone in the diverticulum of Vater.

Chronic catarrhal cholangitis, in addition to the persistent jaundice and paroxysmal pain, is characterized by *ague-like attacks*, consisting of chills, fever, and sweats. These occur at surprisingly regular intervals, resembling in this respect the quotidian, tertian, and quartan spells of intermittent fever, with which the condition has been confounded. They may occur for weeks at a time and then remit. *Pain* is commonly associated with the ague-like spells, but is not always present. The chills may be extremely severe, the sweats also, and the *fever* correspondingly high, the temperature sometimes reaching 105° F. (40.5° C.). The *jaundice* usually deepens after an attack. There may be *nausea* and *vomiting*. The duration may be indefinite from a few months to years, and the patient may yet recover; or he may perish, although the exhaustion is extremely slow and the effect on the general health barely appreciable from week to week. The fever is probably irritative, although it has been ascribed to the omnipresent organism—*bacterium coli commune*. There is sometimes slight enlargement of the liver, appreciable to physical examination, and in long-protracted cases some fibroid induration may be expected to take place. The stools are sometimes bile-stained, at others not. There is occasionally enlargement of the spleen.

The following are Naunyn's distinguishing signs of stone in the *common duct*: "(1) The continuous or occasional presence of bile in the feces; (2) distinct variations in the intensity of the jaundice; (3) normal size or only slight enlargement of the liver; (4) absence of distention of the gall-bladder; (5) enlargement of the spleen; (6) absence of ascites; (7) presence of febrile disturbance, and (8) duration of the jaundice for more than a year."

Osler* has formulated the following symptom-group for the ball-valve stone commonly found in the diverticulum of Vater, but occasionally also in the common duct itself: "(a) Ague-like paroxysms, chills, fever, and sweating—the *hepatic intermittent fever* of Charcot; (b) jaundice of varying intensity, which persists for months or even years, and deepens after each paroxysm; (c) at the time of the paroxysm pains in the region of the liver, with gastric disturbance. These symptoms may continue intermittently for three or four years without the development of suppurative cholangitis. An important diagnostic sign of obstruction of the common duct by stone is the absence of dilatation of the gall-bladder—Courvoisier's rule. It would appear somewhat unaccountable that obstruction by other causes is more frequently followed by dilatation of the gall-bladder than obstruction by calculus. Thus, Ecklin found that of 172 cases of obstruction of the common duct by calculus, the gall-bladder was contracted in 110, normal in 34, and dilated in 28. Of 139 cases of occlusion of the common duct from other causes the gall-bladder was contracted in 9, normal in 9, and dilated in 121.

(b) *Suppurative cholangitis* is marked symptomatically by a fever which is more of the septic type, with remissions rather than intermissions. The jaundice is less marked, the liver is tender and enlarged, the duration of the disease shorter, and termination fatal. The inflammation involves more or less the ducts of the liver, whence it may extend into the liver substance or gall-bladder, causing abscess of the liver and empyema of the gall-bladder.

Other Remote Results of Gall-stone Impaction.—Rarer terminations of impacted gall-stones are the various forms and situations of biliary

* See paper by Osler on "Fever of Hepatic Origin, Particularly Intermittent Pyrexias Associated with Gall-stone," "Johns Hopkins Hospital Reports," vol. ii., No. 1, 1890.

fistulæ, mentioned when treating of the morbid anatomy. Some more detailed reference to these fistulæ should be made. Much has been added to our knowledge of the subject by the industry of Prof. L. G. Courvoisier of Basle.* Courvoisier collected 499 cases of ulcerative perforation of the biliary passages of which 70 occurred directly into the peritoneum, while in 49 cases there was encapsulated abscess, and in 3 there was retroperitoneal perforation. Between the biliary passages themselves were 8 cases: this perforation was found directly from the gall-bladder into the substance of the liver (4 cases); into the hepatic duct (2 cases), into a diverticulum of the common duct (1 case), or between the intestinal and hepatic parts of the common duct (1 case). Perforation between the biliary passages and portal vein was found in 5 cases, if the celebrated case of Ignatius Loyola, about which Courvoisier expresses some doubt, be included. Openings between the biliary passages and gastro-intestinal canal are not uncommon (137 cases); most frequently between the bile passages and duodenum, of which there were 83 cases, of which 73 were between the gall-bladder and the duodenum, while 10 were between the common duct and duodenum. From the biliary passages into the stomach there were 13 perforations; into the jejunum one, ileum one, colon 39. As might be expected, perforation takes place most frequently from the intestinal part of the duct, the stone first lodging in the diverticulum of Vater. Perforation into the urinary passages was found in 7 cases and into the pleura and lungs in 24 cases. To these last J. E. Graham † added 10 cases of broncho-biliary fistula. Finally, there may be fistulous communication between the biliary passages and the external integument, Courvoisier having collected 196 cases, in 49 of which the communication was in the right hypochondrium, 36 at the border of the ribs, 49 at the navel or in its vicinity, 17 in the right mesogastrium, 10 in the right iliac region, and 6 in the epigastrium. Very interesting in this connection is the fact that out of 169 cases in which the sex was noted, 126 were women and 43 men. Among other remote results are septic cholecystitis, associated with high fever, intense prostration, and death from fatal peritonitis; empyema of the gall-bladder, already alluded to as a result of suppurative cholangitis; the latter is commonly associated with gall-stones. Calcification of the gall-bladder is a frequent termination of purulent inflammation. It is present in two forms: first, as a simple incrustation of the mucosa with lime salts, and, second, as a true infiltration of the whole thickness of the wall.

Atrophy of the gall-bladder is not infrequent and may succeed on *hydrops vesicæ felleæ*. I have seen many gall-bladders which did not hold more than a dram (4 c. c.) or two of bile, and sometimes there is a mere remnant left in the shape of a fibroid mass; at other times the shrunken bladder closely embraces a gall-stone of large size. Gall-stones are occasionally found in diverticula of the gall-bladder. Suppurative phlebitis and abscess of the liver may also be due to gall-stone, causing a puriform thrombus in an adjacent branch of the portal vein.

In other instances the gall-stone is of such size as to obstruct the bowel when discharged into it, although it may have passed through the natural channel, as evidenced by dilatation of the common duct. But for the most part such discharge is by ulceration into the intestinal tract. This subject has been sufficiently considered when treating of obstruction of the bowels.

Diagnosis and Prognosis.—There may be some difficulty at first in the

* Casuistisch-Statistische Beiträge zur Pathologie und Chirurgie der Gallenwege, Leipzig, 1890.
 † Transactions of the Association of American Physicians, vol. xii., 1897.

diagnosis of hepatic fever, but the persistent jaundice, the ague-like paroxysms of chills, fever, sweats, and pain are a combination of symptoms belonging to no other condition. A *cancer of the gall-bladder*, which will form a tumor in the same locality, is much more tender; it is harder and more uneven, and jaundice is invariably associated with it, while the patient is much more seriously ill and declines more rapidly. There should be no confusion with a *movable kidney*, which furnishes a different physical condition. An aspirator needle may be used to confirm the diagnosis. The suppurative form is characterized by the more continuous fever and the more serious aspect of the septic state, its shorter course, and its ultimate fatal termination. The catarrhal form is less serious and quite often terminates favorably.

Treatment of Impacted Gall-stone and its Complications.—The first indication is the relief of pain. This is best accomplished by the hypodermic injection of morphin, the action of which is favored by combination with atropin. Scarcely less than 1-4 grain (0.0165 gm.) with 1-150 grain (0.0005 gm.) of atropin suffices, and this must often be repeated. The use of anodynes must be kept up as long as needed. The atropin favors the relaxation needed to release the calculus. The severest cases may require the inhalation of a few drops of chloroform pending the action of the morphin.

Whether anything else can be done toward releasing the stone is not established. The nausea and vomiting, which are so often symptoms, sometimes relieve the pain by the relaxation they produce, such relaxation being at times sufficient to favor the onward movement of the stone. Anesthesia by ether or chloroform may act similarly, and the inhalation above suggested while waiting for the morphin to act favors such relaxation. Hot baths or fomentations applied to the region of the liver may also be similarly effective.

Some solvent for the stone is constantly inquired after. Ether, turpentine, and sweet oil, although lauded for this purpose, have been tried and found wanting. Durandé's remedy consists of turpentine one part, ether four parts; dose, fifteen drops three times a day. It is useless.

To relieve the itching caused by the deposit of pigment in the skin, which is sometimes very annoying in chronic cases, the hot pack on alternate days or even every day is serviceable. A very efficient local application for this purpose is a mixture of 7 1-2 minims (0.5 gm.) of carbolic acid, two fluid drams (8 c. c.) of glycerin, and six fluid drams (24 c. c.) of water. It should be applied with a sponge and allowed to dry on the skin.

The free use of alkaline mineral waters does seem to favor the dislodgment of the stone, especially if the authorities at Carlsbad are to be relied on, who claim the discharge of immense numbers of biliary calculi under the use of Carlsbad water. Certainly no harm can attend its use, and when within the power of the patient to get it, it may be freely taken. The same is claimed by the physicians at Vichy for the Vichy waters—true alkaline waters. In this country, however, the Saratoga waters may be used instead. These waters are saline and not alkaline waters, but they seem to fulfill much the same indications. Those containing the largest proportion of alkaline carbonate are to be preferred. The waters of Vals—also true alkaline waters—are recommended for the same purpose.

Surgical procedures have of late been availed of even with a view to exploration, and if done by competent surgeons with due antiseptic precautions, cannot be regarded as more dangerous than most abdominal sections. The curative measure first suggested by Marion Sims consists in removing

the impacted stone and emptying the gall-bladder of others. At the present day the gall-bladder itself is being successfully removed. Under operative procedure is included aspiration of the dilated gall-bladder, which is justified in the event of a positive diagnosis, though it has been followed by a fatal result. A carefully conducted exploratory *section* is little more dangerous, but, on the other hand, should not be done until the case has assumed some chronicity. Nothing is gained at the present day by exploratory *puncture*, but it is interesting to know that it was done by the elder William Pepper in 1857, and by Roberts Bartholow in 1878.

The *preventive treatment* is important, and although an attack of biliary colic very commonly does not take place until a number of stones have accumulated in the gall-bladder, so that the descent of one is apt to be followed by that of another, prophylaxis should still be availed of. To this end diet is important. The patient should eat sparingly of hydrocarbons and carbohydrates, omitting every form of fat, alcohol, sugar, and starch. Meat, cheese, and gluters, on the other hand, are allowable.

The alkaline and saline mineral waters are more especially indicated between the attacks than during them, and their more or less continued use is advisable, especially in the morning, when their efficiency is also increased by their being taken hot. The sodium salts have considerable reputation for their efficiency in preventing the concentration of bile and formation of gall-stones, having been long ago recommended by Prout. The phosphate is the modern favorite, in dram doses in the morning, or more frequently, but the sulphate is more constant and more potent in its results, and little, if any, more unpleasant. The sodium salicylate has a similar reputation, and may be used when no effect on the bowels is desired. By either of the former or by the aperient mineral waters a daily action of the bowels should be secured, while a proper hygiene of the body, in which daily exercise, bathing, and friction play a conspicuous part, is to be constantly maintained.

I have been in the habit of placing my patients, between attacks, on the succinate of sodium, in doses of five grains (0.32 gm.) three times a day, and it has so happened that I have seldom met a recurrence in one of these cases, although many of them passed out of my observation and may have had attacks without my knowledge.

ACUTE INFECTIOUS CHOLECYSTITIS.

SYNONYM.—*Acute inflammation of the gall-bladder.*

Definition.—Inflammation of the gall-bladder due to infection by pathogenic bacteria.

Etiology.—The most frequent predisposing condition which leads to infection of the gall-bladder is probably biliary calculus, the stone being lodged either in the gall-bladder or some one of the biliary ducts, the vulnerability of the mucous membrane of the gall-bladder being thus increased. But any obstructive cause, such as inflammatory adhesion, or even inflammatory swelling of the mucous membrane of the cystic duct, may be such cause—facilitating bacterial infection. Adhesive inflammation between the gall-bladder and intestines, however induced, is a rare cause, the process extending inwards through the peritoneum. Lithiasis is not, however, necessary to produce infection. Pathogenic bacilli may act independently

of predisposing cause. Indeed, gall-stones themselves are a result of bacterial invasion. The infecting bacterium may be any one of the pathogenic bacteria infesting the small intestine, but recent observations have shown the bacillus of typhoid fever and the colon bacillus to be probably the most frequent, although the pneumococcus, staphylococcus, and streptococcus have also been found to be the infecting agents.

Morbid Anatomy.—This varies with the virulence of the inflammation. In the severer cases there is distention of the gall-bladder with mucus, muco-pus, or pus; at times its contents may be hemorrhagic. Perforation and gangrene have been the first indications of the presence of the disease. There may be adhesion between the gall-bladder and colon or omentum.

Symptoms.—The most invariable symptom is pain, which is commonly sudden and sometimes paroxysmal. It is situated to the right of the median line at the border of the thorax; is attended by fever, sometimes preceded by chills and followed by sweats. So many abdominal conditions, however, cause pain that it alone is not distinctive. Tenderness, less circumscribed than might be expected, is invariably present. Jaundice is not a frequent symptom, never unless the infection involves the hepatic duct or common duct. Vomiting, on the other hand, is very common and often severe. It, too, may be paroxysmal. Certain cases are fulminating, and it may be impossible to get the surgeon soon enough to avert perforation and a fatal termination. On the other hand, many mild cases occur, like one seen with Dr. Thomas Potter, of Germantown, succeeding a relapse of typhoid fever after a normal temperature had been maintained for several days. After recovery from this relapse, there occurred suddenly a chill, sharp pain in the region of the gall-bladder, and rise of temperature. These symptoms subsided in four or five days, to be followed by another attack in which, instead of a chill, there was simply chilliness and with pain and fever less marked; again, after a couple of days, a return of pain with sudden rise of temperature but no chill, again disappearing in a few days. The distended gall-bladder may sometimes be felt. The pulse is sometimes very slow, as in a case reported by the late Frederick A. Packard, where the rate fell to 48, and another seen with Dr. Markley, of Camden, N. J., in which it fell to 40. It is seldom over 100. In Dr. Packard's case there was no fever, in that of Dr. Markley the temperature rose to 103° F. (39.4° C.).

Symptoms may arise from adhesions with adjacent organs, chiefly pain, but sometimes also a dragging sensation. These are commonly part of a chronic condition. Constipation is also a symptom to be expected. In fact, some cases have been treated for obstruction of the bowel, for appendicitis, and more rarely for pancreatitis.

Diagnosis.—Since attention has been directed to the subject, the diagnosis in many cases has become easy. In others it still remains difficult or impossible. Given a case of typhoid fever in which, especially during convalescence, a chill, fever, and sweat make their appearance and there is pain in the region of the gall-bladder, we may infer reasonably the presence of cholecystitis. The same inference may be made if these symptoms occur in a case of chronic cholelithiasis. The presence of an actual tumor at the seat of the gall-bladder is even more confirmatory, but in my experience it is not often easy to recognize a distended gall-bladder through the abdominal wall unless it be of considerable size. Circumscribed tenderness is more frequent. The severity of the attack cannot always be inferred from the early symptoms, but as there are a good many mild cases, a diagnosis of

cholecystitis need not necessarily cause alarm. It should be remembered that jaundice is not a frequent symptom, indeed, it is a rare symptom.

As to differential diagnosis, the conditions with which it has been confounded are *appendicitis*, especially when the appendix happens to be under the liver, as it not very rarely is, *pancreatitis*, *localized peritonitis*, pyonephrosis and inflammatory thickening about the pyloric orifice of the stomach and the duodenum. In the absence of the predisposing conditions referred to, these lesions are sometimes difficult to differentiate. Disease of the head of the pancreas is much more frequently associated with jaundice than is cholecystitis. If a tumor is present in pancreatitis, it is fixed and immovable. It is not usually movable in cholecystitis. An exploratory operation should not be long delayed as perforation of the gall-bladder may precipitate a fatal issue. In cases like three narrated by Maurice H. Richardson,* in none of which was there history suggesting gall-stones and where the symptoms, including pain, vomiting, fever, and tenderness over the appendix, were so suggestive that an incision was made in that quarter, a diagnosis of cholecystitis is impossible. It is difficult to see how anything but appendicitis could be expected in such cases.

Prognosis.—This depends, of course, upon the severity of the case and the promptness of operative interference. There appear to be a good many mild cases which seemingly do not go beyond catarrhal inflammation.

Treatment.—There is really no medical treatment except the symptomatic, and the patient recovers through inherent tendencies, or his life is saved by operation and drainage. In gangrenous cases even operation fails to save some, but all cases demanding operation have the chances of recovery increased by promptness. Richardson says that acute cholecystitis demands interference even more strongly than appendicitis. Counter-irritation by mustard or hot fomentations may be applied to the region of the gall-bladder to relieve pain. Nausea and vomiting are among the most difficult symptoms to relieve. It is a reflected nausea like that of appendicitis. Local applications of ice, or at times the opposite treatment by heat, pieces of ice swallowed, champagne, cold effervescing waters may all be tried. The blister applied to relieve pain may also check the nausea and vomiting. Calomel in hourly doses of 1-10 gr. (.0066 gm.) to 1-5 gr. (.0132 gm.), applied dry on the tongue, should be given in connection with other remedies.

CANCER OF THE GALL-BLADDER.

Etiology and Morbid Anatomy.—Though rare, this affection has excited much interest and has been thoroughly studied, with widely different results in some points. Thus, John H. Musser, in a study of 100 cases, found it three times as frequent in women as in men, while Courvoisier, in a study of an equal number, found it five times as frequent among men.

It is usually primary, when it commonly begins in the fundus. At other times it occurs by contiguous invasion, either from the liver or adjacent abdominal organs. Cancer may also extend from the gall-bladder to adjacent parts. The primary form is associated in at least 87 per cent. of all cases with biliary calculi, and there has been much discussion as to which

* "Acute Inflammation of the Gall-bladder," "Am. Jour. Med. Sci.," June, 1898.

is primary, the gall-stone or the cancer. Zenker and others regard the cancer as secondary, starting in the ulcerative and cicatricial tissue caused by the stones, as is thought to be the case in some instances of cancer of the stomach. This, too, may account for the greater frequency of the disease in women, if such is the case, since women are much more commonly the subjects of gall-stone. It seems reasonable to regard the biliary calculi as secondary to the cancerous disease which may produce changes in the composition of the bile, and I am inclined to agree with Musser that the gall-stones are only a possible exciting cause of the cancer.

A more or less hard, solid, irregular, and fixed mass is the form assumed by the cancer.

Symptoms.—*Jaundice* is absent so long as the disease is limited to the gall-bladder, but as soon as the biliary duct or the common duct is involved it ensues, so that jaundice is present in 69 per cent., gradually increasing in intensity. There is great *tenderness*, with *pain*; *vomiting*, sometimes of blood, *bloody stools*, and *dropsy*, at times succeeded by the *cancerous cachexia*. But none of these is distinctive, being found in cancer of the pylorus, duodenum, and transverse colon. The presence of a hard, uneven, and tender tumor in the neighborhood of the gall-bladder, and which moves with the liver in respiration, confirms the suspicion. This has, in fact, been found in about 69 per cent. If the disease is seated in the cystic duct, the enlargement of the gall-bladder is comparable to that due to obstruction in that duct from other causes, and may be marked.

Diagnosis.—This is sometimes difficult. Pain and tenderness are more marked than in most other affections of the liver, except cholecystitis. Fever and rigors are exceptional and point rather to infectious disease of the gall-bladder or ducts.

Treatment.—The treatment can only be palliative.

AFFECTIONS OF THE BILE DUCTS.

CARCINOMA OF THE BILIARY PASSAGES.

Cancer of the bile-ducts may be primary or secondary. In either event the first symptom is usually *jaundice*, which grows deeper and deeper until the skin may assume an almost bronze-like hue. A *cachexia* rapidly develops. There are pain and tenderness and moderate enlargement, but nothing more destructive than the progressive jaundice, which never grows better. The disease often escapes recognition until an autopsy reveals it. Cancer may invade the bile-ducts from the gall-bladder and possibly from primary or secondary cancers in the parenchyma of the organ. The relation of the morbid growth to gall-stones in its vicinity is governed by the same laws as that between gall-stones and cancer of the bladder. The discussion need not, therefore, to be repeated here.

STENOSIS OF THE BILIARY DUCTS.

Stenosis, or more or less incomplete occlusion of the common duct, may be due to inflammatory adhesion or to compression from without. Sometimes it follows the ulceration attending the passage of a gall-stone. Exter-

nal pressure may be produced by morbid growths and other causes alluded to on p. 436. Notably, cancer of the pancreas is one.

Cicatricial contraction the result of perihepatitis, syphilitic disease, perforating duodenal ulcer, and cholelithiasis should also be mentioned as a cause of external compression of biliary passages, to be recognized, if at all, by aid of the associated symptoms of the disease causing it. In the first there may be a peritoneal friction in the neighborhood of the liver, audible and palpable.

PARASITES.

Parasites may enter the larger biliary passages and produce obstruction. Such are echinococci which may enter the ducts primarily in the larval state and develop there the *hydatid* cyst with resulting obstruction; or, as is more frequent, the sac perforates or compresses a duct in the course of its growth. The other symptoms of echinococcus disease are added to those of obstruction thus produced, or the cysts may appear in the stools, vomited matter, or expectoration. Cases are reported in which the *distoma hepaticum* has been found lodged in the hepatic duct, and *round worms* in the common and hepatic ducts. A remarkable specimen, containing a number of lumbricoids lodged in these ducts, is in the Wistar and Horner Museum of the University of Pennsylvania. The symptoms of these last conditions would be undistinguishable from hepatic obstruction from other causes.

DISEASES OF THE BLOOD-VESSELS OF THE LIVER.

HYPEREMIA.

Passive Hyperemia—Red Atrophy.

The hyperemia of the liver which is of chief clinical importance is passive hyperemia.

Etiology.—It is always due to obstruction to the movement of the blood towards or through the heart. Valvular heart disease is the most frequent cause, though diseases of the lungs, such as emphysema or cirrhosis, intrathoracic growths, diseases of the pleura, compression of the vena cava, or other cause resisting the movement of the blood through the organ are all competent to produce passive hyperemia of the liver.

Morbid Anatomy.—The appearances of the organ after death are determined by the duration of the congestion. If it has been of short duration, the liver rapidly assumes its natural size and appearance after death. Even in long-continued passive congestion the liver after death becomes very much smaller than during life, by reason of the emptying of the blood-vessels, which rapidly succeeds death. In other respects, however, after prolonged hyperemia it presents decided changes. It is dark in color, and the vessels still contain an excess of blood, but the *intra*lobular vein—*i. e.*, the central vein of each lobule—and its adjacent capillaries contain most blood, contrasting strongly with the peripheral or *inter*lobular vessel and its adjacent capillaries. There is thus produced in one way that alternation of dark and light tint which constitutes the *nutmeg* liver and which is particularly con-

spicuous on section. It becomes even more marked at a later stage, when the organ, in its ultimate atrophy, becomes reduced in size, constituting the so-called *red* or *cyanotic atrophy* of the liver,—the atrophied nutmeg liver,—the histology of which exhibits a destruction of the cells and capillaries in the center of each lobule and a deposit of dark pigment in their places. In the liver thus atrophied the blood-vessels also share in the destruction, and short cuts are established between the branches of the portal vein and hepatic vein, while the latter may also become dilated. The exterior of the liver is smooth, and the organ differs in this respect from the cirrhotic liver, though there is sometimes a slight overgrowth of the interlobular connective tissue.

Symptoms.—The liver at first is *enlarged* and *tender*—sometimes very much enlarged and exquisitely tender. The lower border, as determined by percussion, may be as low as the umbilicus and even lower. It may be the seat of *pulsation*, due to regurgitation of blood into it from the right heart. This pulsation is to be distinguished from a motion communicated to the liver by the action of the heart. In the true pulsation the whole liver seems to dilate, and does dilate as the blood flows back into it, as contrasted with the downward movement communicated by the heart. Very characteristic of this enlargement is the changing size of the organ *pari passu* with the degree of congestion, whether spontaneous or the result of treatment.

Ascites is also a symptom. It does not occur, however, until a marked degree of passive hyperemia or *secondary* contraction is attained. The ascites is partly the result of the general stagnation always present, and partly of the congestion of the portal system due to the backing of the blood of the hepatic vein into it. *Jaundice* is another rather rare symptom. It is due to the compression exerted on the fine interlobular gall-ducts by the overdistended interlobular capillaries, thus producing an obstructive jaundice.

Scanty urine of high specific gravity is also a symptom, while *hyperemia with enlargement of the spleen* and *hyperemia of the mucous membrane of the stomach* are constant, as a result of the same cause.

Treatment.—The treatment of passive hyperemia is the treatment of the condition causing it. Most frequently the cause is heart disease, and when the latter is amenable to digitalis or other heart tonics, the passive hyperemia disappears with the restoration of compensation. Simultaneously the urine is increased, and the general dropsy, ascites, and hydrothorax disappear. Such treatment is aided also by depletion from the portal side by purgatives. Blue mass is the type of these, but colocynth, elaterium, and compound jalap powder, or the simple salts, are also efficient. It sometimes happens that the general dropsy in these cases is dispersed by treatment, but the ascites remains, in which event we must suppose the simple passive congestion to be combined with some degree of atrophy, when the dropsy is more likely to remain. Treatment should now be supplemented by hydragogue cathartics, or, still better by tapping, followed by dry diet and the hydragogues. A dram (4 gm.) or more of compound jalap powder may be given each morning fasting, or elaterium, 1-6 grain (0.01 gm.) every three hours, until the bowels are moved.

It was suggested by George Harley to deplete the liver under these circumstances, and it has been put into practice by East Indian physicians, it is said, with good results.

Active Hyperemia.

Definition.—This is a much less important condition than passive hyperemia, and, indeed, is rarely recognized. A physiological hyperemia of the liver takes place after each meal, which may be exaggerated and even continuous in those who overeat and overdrink habitually. Such hyperemia may lead to structural change, consisting ultimately in interstitial growth. Like this, also, is the hyperemia which is associated with diabetes mellitus, and which is the associated condition of many glycosurias, whether experimental or the result of disease affecting the diabetic center. Such is a vicarious hyperemia said to take place during suppressed menstruation and after cutting off a hemorrhoidal flux.

Active hyperemia does not, however, present any symptoms referable to it, unless it be that the dull ache and full feeling sometimes felt in the right hypochondrium be caused by such condition.

Treatment.—The treatment of fluxion to the liver must consist of measures which tend to diminish this, mainly the substitution of a scanty for an overabundant diet, simple and easily-digested foods, dilute milk, and thin broths, and the avoidance of fats, alcohol, and sugar.

THROMBOSIS AND EMBOLISM.

The portal vein is the seat of thrombosis and of inflammation, constituting pylethrombosis and pylephlebitis. The hepatic artery also becomes rarely the seat of aneurysms.

Pylethrombosis.

Thrombosis takes place in the smaller branches of the portal vein, which are constantly being obliterated in the course of cirrhosis of the liver. Larger branches are sometimes invaded by cancer, or a gall-stone may be admitted into one of them by ulceration, or the lodgment of a parasite may be the focus about which a coagulum may form, while thrombosis may also be favored by the pressure incident to the encroachment of a neighboring tumor.

Symptoms.—These include those to be detailed when treating of cirrhosis—viz., ascites, hyperemia in the parts behind the obstructed vessel, with this difference, that the symptoms appear more or less suddenly and severely. It is mainly by the suddenness and intensity of the symptoms that we are led to suspect thrombosis, especially if it be associated with any of the previously-named conditions capable of producing it. In such an event the symptoms would come about in the course of a few days, instead of weeks and months. A *caput medusæ* thus rapidly produced would mean that the thrombus had formed, not in the portal vein itself, but more peripherally, causing the para-umbilical veins to be filled from the peripheral branches. These come off the portal vein in the suspensory ligament, and pass out to the neighborhood of the navel by two branches communicating with the epigastric and internal mammary vein.

When pylethrombosis occurs, it sometimes happens that a complete collateral circulation is established, the thrombus undergoing the usual

changes, while the portal vein may be ultimately converted into a fibrous cord. Osler reports such a case, in which compensation finally failed, and the usual symptoms, including hematemesis, supervened, and the patient died.

Pylephlebitis.

Mild grades of pylephlebitis probably succeed the thrombosis referred to, but they are of no consequence unless the thrombus is septic. Hemorrhagic infarct does not usually succeed the lodgment of an embolus in a branch of the portal vein, because of the free anastomosis of its branches with those of the hepatic artery, by which the lobular capillaries are supplied. It does, however, sometimes occur. Here again the results are not serious, so long as the embolus is not septic. Much more serious is suppurative phlebitis, the result of septic embolism, or thrombosis arising from an inflammatory focus somewhere in the portal area, as in the bowel dysentery, or in the territory of the umbilical vein of the new-born child. Pylephlebitis is one of the causes of abscess of the liver. It is associated with the usual signs of septic infection—viz., *chills*, *remittent fever*, and *sweats*, while the symptoms which point to the liver are *pain* in that neighborhood, *jaundice* in most cases, and the signs of *portal vein obstruction* more or less pronounced. Suppurative peritonitis is also sometimes added. Such phlebitis does not always proceed to the degree of abscess formation before death supervenes. The symptoms of abscess will be considered, when treating of that subject, when, too, attention will be called to the diagnosis between it and suppurative phlebitis, so far as it can be made out.

Other Changes in the Hepatic Artery and Vein.

The artery is sometimes dilated in cirrhosis of the liver; it may be the seat of endarteritis and sclerosis. Aneurysm of the artery is a rare condition. The symptom is a pulsating tumor, which may be the seat of a murmur. In the cases reported there have been hematemesis, bloody stools, jaundice from compression of the biliary ducts, and pain in the neighborhood of the liver due to compression of adjacent nerves.

The hepatic vein is subject to dilatation, alluded to in treating of passive hyperemia; to stenosis, and to thrombosis extending backward from the right auricle.

FATTY LIVER.

Definition.—The term fatty liver is applied to a condition in which the cells of the liver are more or less completely converted into fat. This is accomplished, however, by two distinct processes. In one there is an infiltration of the liver cells with fat drops, which simply push aside the protoplasm and cause its ultimate disappearance by interfering with its nutrition. In the other there is a disintegration or metamorphosis of the protoplasm of the cell into various products, of which one is oil. In the former, fatty infiltration, the cell maintains its integrity, being simply filled with the fat drops; in the latter the cell disintegrates and leaves a residue of which fat is the chief representative. It should be mentioned that some use the term “fatty liver” as synonymous with “fatty metamorphosis.”

FATTY INFILTRATION.

Etiology.—Abnormal fatty infiltration occurs in two ways.

1. In case of overingestion of fat-producing substances, resulting in obesity, of which it is a part, and as the result of which the liver becomes a storehouse for fat. Excessive consumption of alcohol is attended by fatty infiltration, because more carbohydrate is introduced than can be burned up. It is, therefore, stored in the liver cells.

2. In a series of cachectic states, in which oxidation is interfered with and the fat which is ingested is not oxidized, but accumulates in the liver. Such a condition is pulmonary tuberculosis, which is the most common cause of fat-infiltrated liver, except alcoholism.

Morbid Anatomy.—The liver of fatty infiltration is uniformly large, soft, and smooth. Its appearance varies somewhat at different stages. Since the infiltration begins at the periphery of the lobule, we have, in the first stage, a simple distinctiveness of the line of demarcation between the adjacent acini. In the second stage this has become more marked, contrasting strongly with the darker color of the center of the lobule, and producing one form of *nutmeg* liver—as contrasted with the liver of red atrophy, already described in treating of passive congestion. In the third stage the entire acinus is infiltrated, and the whole organ assumes a uniform yellow or brownish-yellow appearance, from complete fatty infiltration of the cells. The organ is also anemic. In this last stage it is that we have the macroscopic changes complete—the softness, the broadened edges, and increase in size, with, however, a decided reduction in specific gravity, so that the whole organ floats when placed in water.

Symptoms.—Outside the physical condition, determined by palpation and percussion, and the causing disease or state, there are no distinctive symptoms. There is no jaundice, and the bile-forming function of the liver seems little interfered with, though the stools are pale. There is no obstruction to the portal circulation, and, therefore, no abdominal dropsy. Percussion recognizes *enlargement of the liver*, which is, however, moderate compared with that of amyloid liver and cancer, extending, as it does, but a short distance below the normal site, where its edge can be felt even through abdominal walls of some thickness. There is no enlargement of the spleen.

Diagnosis.—It becomes necessary to differentiate the enlarged fatty liver from the amyloid liver, which is harder and larger and associated with enlarged spleen and albuminuria. With the hyperemic enlargement of the first stage of cirrhosis it is not likely to be confounded. Such enlargement would be trifling, accompanied by tenderness, and sooner or later succeeded by contraction, while the fatty liver continues to enlarge. From the enlargement due to the cloudy swelling characteristic of the infectious diseases, typhoid and typhus, it is distinguished by the absence of fever and other symptoms of these diseases.

Prognosis.—This depends upon that of the causing disease. The liver of fatty infiltration can be completely restored to its natural condition with the removal of the cause.

Treatment.—The treatment is that of the disease causing it.

FATTY METAMORPHOSIS.

Definition.—This is a much more serious condition, in which the cell protoplasm is directly converted into fat, or rather, perhaps, into a number of products of which fat is one, while the cell undergoes disintegration. It is the effect of some poison, which has its type in phosphorus-poisoning and in the cause, whatever it may be, of acute yellow atrophy of the liver.

Morbid Anatomy.—The liver, instead of enlarging, undergoes rapid reduction in size, or at least, if there is enlargement, it is of such short duration that it is never recognized. The appearance and condition of the liver, to be described under acute yellow atrophy, are those of the liver which is the seat of rapidly progressing fatty metamorphosis.

Symptoms.—They are those of the diseases causing it, and will be described under Acute Yellow Atrophy.

The **prognosis** is fatal and **treatment** is unavailing.

THE AMYLOID LIVER.

SYNONYMS.—*Lardaceous Liver; Waxy Liver; Albuminoid Liver.*

Definition.—In the amyloid liver there is an infiltration, in various degrees, of all the tissues of the organ by the so-called amyloid substance. The blood-vessel walls are the first affected, and by preference those of the intermediate area of the lobule—*i. e.*, that supplied by the hepatic artery, then the central or hepatic vein zone, and finally the peripheral or portal zone. The infiltration begins in the smaller arteries, then invades the cells and capillaries, and in extreme cases pervades all the liver tissue, including connective tissue.

Etiology.—The most usual cause of amyloid liver is prolonged supuration, especially in connection with tubercular disease of the bones. Hence it is found in children who have had hip disease. For the same reason it is found associated, though less frequently than might be expected, with prolonged tuberculosis of the lungs. Syphilis is one of the recognized causes, whence it may arise as a tertiary manifestation or as the result of bone disease incident to it. Rickets likewise produces some cases, and it is also associated, though rarely, with leukemia, the cancerous cachexia, and the infectious diseases.

Morbid Anatomy.—The liver is much enlarged, reaching sometimes enormous dimensions, scarcely exceeded by the largest cancers. Its appearance is waxy or bacony, especially in thin sections. This appearance is partly due to the anemic state of the blood-vessels, whose lumen is encroached upon by the infiltrated walls. The amyloid parts strike a mahogany-red color with weak solutions of iodine. In addition to the change in size and translucency, the amyloid liver is hard and smooth, its border usually, though not always, rounded, and its fissure exaggerated. In certain syphilitic forms its surface is beset with nodules. Instead of being general, the amyloid change is sometimes circumscribed, when it may be associated with red atrophy. It is occasionally combined with fatty infiltration.

Symptoms.—Beyond the *enlargement*, which is usually manifest, the organ extending sometimes as low as the umbilicus, and, in addition to the

symptoms of its causing state, there are none peculiar to the amyloid liver. There is no pain, unless it be the result of an associated syphilitic hepatitis, but there may be a *dragging sensation*, induced by the weight of the organ. There is no jaundice, though the stools may be light-hued, because the secretion of bile is diminished. There is no ascites, except in extreme cases, when it is a consequence of the general hydremia, and not of obstruction in the portal circulation. It is usually associated with *amyloid spleen*, which is enlarged, and with the *amyloid kidney*, which secretes albuminous urine.

Diagnosis.—This is usually easy. The large, smooth, hard organ, the history of the presence of the causing disease, the absence of jaundice and of dropsy, the association of enlarged spleen and albuminuria, admit of scarcely any other interpretation. It is to be remembered, however, that amyloid spleen is not invariably present, and, when present, may be overshadowed and compressed by the large liver. The enlarged liver of leukemia, the result of white-cell infiltration, is not likely to be confounded, because the other symptoms of this affection are so evident. The nodular amyloid liver, due to syphilis, must be remembered as a possibility, and will be referred to again in considering the diagnosis of cancer of the liver.

Prognosis and Treatment.—They are those of the causing disease. I have never seen an amyloid liver reduced to the normal size, yet the absence of symptoms growing out of moderate degrees of it makes practical recovery not impossible.

CIRRHOSIS OF THE LIVER.

SYNONYMS.—*Chronic Interstitial Hepatitis; Gin Liver; Granular Liver; Hob-nail Liver.*

Definition.—Cirrhosis of the liver is a disease characterized by an overgrowth of connective tissue with more or less destruction of the parenchyma of the organ, commonly attended by a harder consistence, sometimes by a reduction of size, at others by enlargement, and at others by no changes in this respect. Too much stress has, perhaps, been laid in the past on shrinking of the organ as a necessary feature of the disease.

Etiology and Pathology.—Alcoholism is the commonly recognized cause of cirrhosis of the liver, though by no means all alcoholics, even the most confirmed, have cirrhosis. Indeed, a large number of drunkards, watched to their death and examined with special reference to this subject, have been found to have normal livers at the autopsy. Hence, some experienced observers, notably Francis E. Anstie and, later, Henry F. Formad, were disposed to deny that the abuse of alcohol ever produces cirrhosis. Even W. H. Dickinson's observations, which were made with the definite purpose of settling the question, were not so conclusive as might have been expected. Thus, he noted in 149 autopsies upon persons connected with the liquor traffic, 22, or only 14.75 per cent., had cirrhosis; while out of 149 otherwise engaged, 8, or 5.1-2 per cent., were thus affected. On the other hand, the studies of the late R. Palmer Howard,* of Montreal, noted below, seem to reaffirm the long acknowledged dictum. The large fatty liver is probably as frequent a consequence of alcoholism as is cirrhosis.

* R. Palmer Howard, "Transactions of the Association of American Physicians," vol. ii., 1887.

Long-continued malarial intoxication and congenital syphilis are considered causes of cirrhosis. Syphilis produces, however, quite a special form of interstitial hepatitis. In his able study of that very interesting class of cases, cirrhosis in children, Dr. Howard found 11 per cent. due to syphilis, chiefly hereditary, while alcohol was still responsible in 15.8 per cent., even in children. Passive congestion due to heart disease or pulmonary obstruction causes some cases, but red atrophy is the more usual form associated with valvular heart disease. This cause I consider more frequent than is commonly supposed. Other causes mentioned are stimulating diet and irritation of the gall-ducts by such agencies as obstructing calculus. Finally, a certain number of cases of cirrhosis are altogether inexplicable.

It has heretofore been thought that most of the causes act through the blood of the portal vein, irritating the connective tissue of Glisson's capsule, which accompanies everywhere the branches of that vessel, causing first a hyperemia, and then a hyperplasia of connective-tissue cells. Thus, the first stage of the disease would be one of enlargement, accompanied often by tenderness. Subsequently, it was supposed, this embryonic connective tissue undergoes organization and contraction, gradually compressing the cells within its grasp and ultimately destroying immense numbers of them; that the reduction in size so often present goes *pari passu* with a hardening of the organ, which is also a conspicuous feature of advanced degrees of the disease. But while cases are met with representing both ends, so to speak, of the process, the initial stage of enlargement and tenderness, and the terminal one of smallness and hardness, few can attest that they have had the opportunity of tracing the one stage into the other in the same patient, though the celebrated Dr. Bright, as far back as 1827, claimed to have traced cirrhosis from the incipient enlargement to the smallness of the later stage. I myself have seen reduction of size succeed on enlargement, but I have never seen the contracted small liver result.

Much more reasonable appears Weigert's conclusion, based on experiment, that the death of the cells is primary and the overgrowth of connective tissue secondary. Acknowledging that the majority of causes which produce the disease, such as alcohol, for example, operate through the portal circulation, it is only reasonable that the cells whose business it is to eliminate the poison should receive the first sting and perish in consequence, and that their place should be supplied by a reactive overgrowth of connective tissue, as Weigert has shown. We may also admit a reactive contracting effect of the new connective tissue on remaining cells, producing thus the death of a greater number.

J. G. Adami's studies "On the Bactericidal Functions of the Liver and the Etiology of Progressive Hepatic Cirrhosis"* tend to support this view. In all the cells of the liver in most instances Dr. Adami finds a few dead bacteria, but in certain cases of cirrhosis, of which he had examined more than twenty livers, he found large numbers of a living bacillus which he regards as one of the many varieties of the colon bacillus.

But poisons do not enter the liver by the portal vein alone. Irritants may enter by the systemic circulation (the hepatic artery), and passively by the hepatic vein and bile-ducts when obstruction occurs in either of these sets of vessels. Cirrhosis of the liver may result from any one of these four anatomical sources, and it may be that each one of these may place

* Read before the British Med. Assoc. at its meeting in Edinburgh, and published in the "British Medical Jour.," October 22, 1898.

a more or less special stamp on the form originating from it, at least at the beginning of the process.

Though occurring in children, cirrhosis of the liver is still a comparatively uncommon disease among them, being rarely met before the age of thirty-five. It is also a disease of men, rather than of women.

Morbid Anatomy.—At least two well-defined varieties of interstitial hepatitis are met, known as atrophic and hypertrophic cirrhosis.

(a) *Of Atrophic Cirrhosis.*—In addition to the hardness and reduced size of the liver, which may fall from its normal weight of four or five pounds (1.8 to 2.2 kilograms) to two pounds (0.9 kilogram) or less, the surface of the organ is rough and uneven. In the formation of these inequalities circlets of parenchyma are replaced by connective tissue, within which the parenchyma remains intact and appears raised. According as the elevations vary in size the liver is described as a *granular* liver, a *hob-nailed* liver, or a *lobular* liver. If the cells are fatty, as is sometimes the case, they are yellow; at other times they are natural in hue; at others, paler. It was on the color of these nodules that Laennec based the name of *cirrhosis*, from the Greek *κίρρος*, reddish-yellow, or tawny. In some instances the cirrhotic liver is quite *smooth*, showing a uniform distribution of the connective tissue through the parenchyma of the organ, appreciable only in thin sections examined by the microscope. As the process extends it involves branches of the portal vein itself in its destruction, and even bile-ducts are obliterated. Amyloid and fatty infiltration may be associated with cirrhosis. Indeed, the atrophic liver is very commonly associated with fatty infiltration, which enlarges the liver to a degree which may overbalance the contraction. The new connective tissue, on the other hand, is richly supplied with blood-vessels from the hepatic artery, and Rindfleisch has suggested that the bile is secreted from this blood, rather than that of the portal vein.

(b) *Of Hypertrophic Cirrhosis—Elephantiasis of the Liver.*—The French clinicians, headed by Charcot and Henoeh, have studied this form most thoroughly. The liver is enlarged, and it is not unlikely that what has been characterized as the first stage of atrophic cirrhosis has sometimes been represented by this form of disease. An important difference between the two forms is that, while in both there is an overgrowth of connective tissue, in hypertrophic cirrhosis the newly-formed tissue exhibits little disposition to contraction. Nor is there any compression of the branches of the portal vein. On the other hand, there is obstruction of the biliary channels, producing the jaundice which is so characteristic a symptom, whence the French investigators would have the disease begin as an inflammation of these passages—a *cholangitis*—and call it "*cirrhose hypertrophique avec ictère.*" It is claimed also by Henoeh that there is a new formation of biliary capillaries. Others hold that this absence of contraction in the connective tissue is exaggerated; that while it is much less marked than in atrophic cirrhosis, it does occur sooner or later if the patient lives long enough. It is said to be further characteristic of the development of connective tissue in hypertrophic cirrhosis that it is more active *within* the lobules. However this may be, the liver, thus enlarged, may weigh from eight to ten pounds (3.6 to 4.5 kilograms). Its color is greenish-yellow or green.

Biliary Cirrhosis.—This term is used by some as synonymous with hypertrophic cirrhosis; but the French clinicians also describe a liver of

increased size, in which the enlargement is ascribed to an overgrowth of interstitial connective tissue, an overgrowth which replaces gaps in the parenchyma destroyed through the toxic effect of bile retained in the ducts. This is followed by a deposit of pigment granules in the interlobular connective tissue and within the acini themselves. It is, therefore, "secondary" to obstruction of the gall-ducts by any prolonged cause, as a gall-stone, tumor, or the like. In such case the liver is larger and harder. This reasoning seems to be sustained by experiment, since ligation of the common bile-duct in animals has been followed by such cirrhosis. I cannot, however, see any essential difference in the etiology and motive of these two forms.

The spleen is found enlarged in most cases of cirrhosis of the liver of any variety which come to autopsy.

Symptoms.—(a) *Of Atrophic Cirrhosis.*—It must be admitted that cirrhosis of the liver sometimes fails to give rise to any symptoms. The early subjective symptoms of this affection are rather the result of secondary conditions caused by it. Among these are, pre-eminently, those of *chronic gastric catarrh, anorexia, nausea, sense of distention, and resulting discomfort.* The gastric catarrh is the consequence of chronic passive hyperemia, due to obstructed movement of the portal blood through the liver. As a result of the hyperemia the mucous membrane of the stomach is more or less constantly covered with mucus, which excites nausea and interferes with secretion of gastric juice. A similar condition exists in the small intestine, causing constipation, which is increased by the deficient biliary secretion. This is further shown by the paleness of the stools. The well-known comforting effect of the early morning "dram" upon the inebriate may be due to some action of the alcohol upon this mucus. The disease is usually afebrile. Occasionally there is slight fever with temperature of 100° to 102° F. (37.7° to 38.8° C.).

The remaining symptoms are also mainly the result of the ligature-like effect of the connective tissue on the portal vessels. *Nasal hemorrhage*, often very obstinate, is one of these. So are *gastric and intestinal* and, more rarely, *esophageal hemorrhages*, these hemorrhages being often enormous and alarming, but really beneficial, by removing the gastro-intestinal congestion. I have, however, had two cases of fatal hemorrhage thus caused. Either one of these forms of hemorrhage may be the very first symptom to attract attention. Uterine flooding also sometimes occurs, and even hematuria. Similarly caused is the *abdominal dropsy*, which is often enormous. Four gallons (15 liters) and more are not infrequently removed at one tapping, and sometimes the fluid, from its weight, bursts through the feeble barrier at the abdominal ring, distending the tunica vaginalis. The navel is often pushed out by the enormous distention.

The surface of the upper abdomen and lower thorax, anteriorly, is marked by *overdistended veins*. This is directly due to the backing of the blood into these veins, rendered possible by the anastomotic communication between the portal and caval circulations. Such anastomosis between the rudimentary veins in the round ligament (branches of the portal vein) and the epigastric and mammary veins leads to enlargement of the superficial branches of the latter, and in extreme cases to the formation of a *caput medusæ* about the navel. Communication between the superior hemorrhoidal vein (a branch of the portal vein) and the middle and inferior hemorrhoidal, and through them with the hypogastric veins and vena cava, produces *hemorrhoids*, a characteristic symptom of cirrhosis. Anastomosis between the

superior gastric vein (a branch of the portal) and the inferior esophageal, whose blood goes to the cava through the azygos and hemiazygos, causes a varicose condition of the veins of the lower end of the esophagus which has resulted in fatal hemorrhage. The overfilling of the esophageal and azygos veins also obstructs the movement of the blood through the intercostal and pleural vessels of the right side, causing right-sided hydrothorax. These dilatations, which have been characterized as "attempts at compensation," are to be distinguished from the more diffuse dilatations of the abdominal veins seen in the flanks, which are due to the pressure on the cava of extreme abdominal dropsy, preventing the return of the blood of the lower extremities to these veins. *Edema of the legs* is, however, much more uncommon than abdominal dropsy, and, when present, depends upon the further pressure exercised by the enormous accumulation of fluid in the abdominal sac upon the returning blood of the lower extremities.

Jaundice is a symptom in atrophic cirrhosis, though the constricting effect of the interstitial tissue upon the gall-ducts would lead us to expect it to be more frequent. It may be because comparatively little bile is secreted. Fagge* reports 34 cases of jaundice out of 130 examined in the postmortem room of Guy's Hospital, rather more than might be expected. *A sallowness of complexion* is also sometimes present, while a *ruddiness of face* is not uncommon.

Physical examination by palpation and percussion discovers a *diminished* area of *hepatic dullness* in atrophic cirrhosis. On the other hand, *splenic dullness* is often *enlarged*, the latter because of resisted return of its blood through the liver, though the same cause which operates in producing cirrhosis may also co-operate to produce splenic enlargement if it be systemic in origin. According to Frerichs, the spleen is enlarged in about one-half of the cases; some even say in three-fourths. In alcoholic cirrhosis especially enlarged spleen is considered evidence of an advanced stage of the disease. It is often impossible to outline either liver or spleen because of the extreme abdominal distention, and tapping must first be resorted to before physical exploration is satisfactory.

The *urine* in atrophic cirrhosis of the liver is generally scanty, of high specific gravity, highly colored, and often loaded with urates, which subside on standing, forming a bulky sediment. The proportion of urea is often diminished, a natural result of the deranged function of the liver, to which modern physiology assigns an important rôle in urea formation. The urine also contains at times bile pigment, but less frequently than in hypertrophic cirrhosis. Blood is also sometimes found in the urine.

Drowsiness and *coma* and even *delirium* are sometimes terminal symptoms, especially in cases where there is jaundice, but also where there is ascites without jaundice. They have been ascribed to cholesteremia.

(b) *Symptoms of Hypertrophic Cirrhosis*.—The symptoms which distinguish this form from the atrophic variety are:

1. The jaundice, which begins with the first vague symptoms of the disease and gradually deepens as the disease progresses. The explanations suggested of this feature of the disease, as contrasted with its absence in atrophic cirrhosis, cannot be said to be altogether satisfactory. It is simply true that in some way there is produced obstruction in the biliary vessels, perhaps by a cholangitis.

2. The absence of hyperemia of the stomach and bowels, of hemor-

* "Practice of Medicine," 1886, vol. ii. p. 306.

rhoids, enlargement of the spleen, and pre-eminently of ascites; or the presence at least of only mild degrees of these symptoms.

3. The presence of tenderness in the liver, in addition to its evident enlargement and smoothness.

4. Certain differences in the urine in the two forms.

It is a well-recognized fact that when there is jaundice the urine is also jaundiced. In *atrophic* cirrhosis jaundice is more infrequent, and when present, say in about one-fourth the cases, it is very slight. The same is true to a less degree of the urine, for while the latter is scanty and highly colored, it less frequently contains bile pigment. In *hypertrophic* cirrhosis, on the other hand, bile-stained urine is more common. Blood is never found in the urine of hypertrophic cirrhosis, while in atrophic cirrhosis it sometimes is in advanced stages, as is also albumin. In atrophic cirrhosis the urea is diminished; in hypertrophic, it is normal in quantity. In hypertrophic cirrhosis the feces are sometimes devoid of bile; at times, not.

Rosenstein has made a study of the blood in hypertrophic cirrhosis, and has found the red corpuscles diminished one-half and the leukocytes relatively increased. He also found it to coincide in certain cases with the hemorrhagic diathesis. Alcohol is said to be even a more important factor in causing hypertrophic than atrophic cirrhosis.

The course of hypertrophic cirrhosis is usually more rapid than that of the atrophic. It may be put down at one or two years, yet in some cases it is very short. Osler mentions a case which proved fatal in ten days; another in three weeks. It may be questioned whether these were not cases of acute yellow atrophy. All cases terminate more or less acutely. Delirium sets in, the tongue becomes dry, the pulse rapid, and the temperature rises from 102° F. to 104° F. (38.9° C. to 40° C.).

Diagnosis.—(a) *Of Atrophic Cirrhosis.*—The diagnosis of cirrhosis of the liver is not usually difficult. If one is satisfied that there is a reduction in the size of the organ, and there are associated with this no symptoms of acute disease and no history of starvation, we may infer scarcely anything else but cirrhosis; and if to this is added ascites, without dropsy elsewhere, the diagnosis is absolute.

Tubercular peritonitis, with its liquid effusion, has been mistaken for cirrhosis, and the wasting which attends advanced stages of the former affection closely resembles that in the latter, but the abdominal tenderness in peritonitis is characteristic, there is fever, and the effusion is never very large. The tuberculin test should be applied in all doubtful cases.

(b) *Of Hypertrophic Cirrhosis.*—Hypertrophic cirrhosis is to be distinguished from cancer of the liver, amyloid liver, multilocular echinococcus disease, and the liver of obstructive jaundice. In *cancer* there is no splenic enlargement, ascites is more frequent, the liver is more uneven, and the patient is older, while in hypertrophic cirrhosis we have also the history of alcoholism.

In *amyloid* liver there is also splenic enlargement, but there is no pain, no jaundice, and we have the etiological history peculiar to amyloid disease.

Multilocular hydatid disease in the liver may present almost identical symptoms, including jaundice and splenic tumor, but in addition there are the nodules on its surface which soften with time.

The liver which is associated with *chronic biliary obstruction* and secondary cirrhosis, while somewhat enlarged, is not nearly so much so as in hypertrophic cirrhosis. Hepatic colic has been present at some time in the course of the disease. It is also hard, and accompanied by marked jaundice

and other evidence of hepatic obstruction. Its course, while slow, is more rapid as a rule than that of hypertrophic cirrhosis, while the liver also after a time diminishes in size.

Prognosis.—The prognosis of cirrhosis of the liver is unfavorable if restoration of the normal organ be the object. A liver once the seat of interstitial hepatitis can probably never resume its normal histology. Yet the liver has a good deal of elasticity of function, and if the cause of the condition, supposing it to be alcoholism, is removed and the contraction be not too far advanced, the patient may be restored to comparative health. Generally, however, the course of cirrhosis is from bad to worse, although it may be a slow course, and the patient finally dies of exhaustion and cholemia.

It only rarely happens that death is caused by the copious hemorrhages from the stomach and bowels which sometimes occur. I have already referred to two cases in my practice. On the other hand, they frequently relieve the portal congestion, thus giving to the patient a new lease of life. He may live many years in comparative comfort.

Treatment.—The treatment of cirrhosis of the liver resolves itself into two parts—first, the relief of the symptoms, and, second, the restoration of the organ to its normal state.

Toward the first result the removal of the cause is indispensable. The alcoholic must stop drinking. This, after some temporary inconvenience, of itself brings alleviation. But the effect of gastric congestion remains in part, and sufficiently to cause want of appetite, nausea, unpleasant taste in the mouth, and a general disgust of one's self and everyone else. The mucous membrane of the stomach is swollen, and probably bathed with mucus. The latter can be removed by free drinking of alkaline mineral waters before meals, such as those of Vichy, Vals, and Carlsbad, the effect of all of which is increased when hot. Here, too, as in gastric catarrh,—it is really gastric catarrh we are treating,—the hot-water treatment is often highly useful by ridding the stomach of mucus. A tumblerful, as hot as it can be borne, is taken slowly before breakfast, or before each meal. Its effect is often highly beneficial. I know no additional explanation of its action unless it be that it may likewise stimulate the secretion of gastric juice. Lavage also relieves this condition and its consequent symptoms.

The congestion which is responsible for this secretion must be removed. This is best done by the saline and mercurial purgatives. Five to ten grains of blue mass at bedtime, followed by a dose of sulphate of magnesium in the morning or of Hunyadi or Friedrichshalle water, will deplete the engorged veins and relieve the symptoms for the time being. The mineral waters of Saratoga in this country, some of which are also purgative, are very useful for the same purpose. A course at Saratoga is greatly appreciated by the confirmed free drinker, and he is always better for some time after it. The hot saline and sulphur waters at Greenwood, Colo., are similar in their effects.

Finally, foods which make the least demand upon the stomach are to be used. Fatty matters are especially contra-indicated. In advanced stages milk and Vichy, peptonized milk, and beef peptonoids may be assimilated when other foods cannot be managed by the feeble digestion, but even these are absorbed with difficulty as long as the mucous membrane of the bowels is much congested.

The abdominal effusion is combated by the purgatives alluded to, and diuretics may be added; of these the acetate of potassium seems more efficient than the bicarbonates and citrates where dropsy is due to hepatic affec-

tions. Perhaps this is because in large doses it has also some laxative effect. Theobromin is often an efficient diuretic in these cases, especially when the heart is in good condition. When the abdominal effusion becomes large, it must be removed by tapping, although the reaccumulation may be very rapid and it may have to be repeated many times. Recently operation has been suggested for permanent cure of abdominal effusion due to this cause.

Can anything be done to remove the growth of the connective tissue and promote the redevelopment of the destroyed parenchyma? Presumably, if the former could be accomplished, the latter may take place, for there is evidence to show that the liver structure may be reproduced. Theoretically, iodid of potassium is a remedy which should melt away the overgrown connective tissue. Practically, it is extremely doubtful whether it does. I have never seen such effect, nor can I point to any reliable observations that affirm it. There may be, however, and to such an end it is right to use the drug in small doses, which, to produce any effect, should be long continued. It is also a diuretic. There is reason to believe that the iodid is more efficient when taken freely diluted and on an empty stomach than in larger doses after meals. Thus administered, three to ten grains (0.2 to 0.66 gm.) may be regarded as a sufficient dose.

SUPPURATIVE HEPATITIS.

SYNONYM.—*Abscess of the Liver.*

Etiology.—The vast majority of abscesses of the liver, some would say all of them, are traceable to causes which, in one way or another, are associated with microbic origin. Even traumatic abscess, which is of admitted occurrence, is ascribed to an associated infectious agent. The possibility of abscess excited by simple chemical, as contrasted with bacterial cause should at least be mentioned. Most abscesses of the liver arise by infection from the portal area. These are *thrombotic*, *embolic*, or *amebic*. The *thrombotic* are caused by infectious thrombus, which, starting in the venules of an area drained by the portal vein, extends thence to the branches of the portal vein in the liver, where it gives rise to a suppurative pylephlebitis. Such an area is the colon when the seat of dysentery, the rectum by its hemorrhoidal veins, or the neck of the bladder. More frequently a fragment of such thrombus lodges in a branch of the portal vein and starts an abscess, constituting the embolic origin. Or the *ameba coli*, which is the cause of amebic dysentery, is transferred from its primary seat in the intestine into the liver. A similar mode of origin of abscess is by an umbilical phlebitis in the newborn infant.

Abscesses of the liver may also be caused by infectious emboli arising in the left heart, the pulmonic or systemic circulation, reaching the liver *via* the hepatic artery. These emboli mostly originate in the lungs or left heart, but may arise beyond, the condition being that they are small enough to pass through the capillaries of the pulmonary artery. Such would be the abscesses caused by injuries to the scalp or to bones of the skull, or from seats of osteomyelitis elsewhere, all of which are acknowledged to be rare causes of abscess of the liver. Septic emboli, producing abscess of the liver, may arise from the left heart in cases of ulcerative endocarditis. These are among the rare causes of abscess of the liver. Even a non-infectious embolus may

excite an abscess if brought into association with pyogenic organisms entering the liver in another way. Such organisms may enter the liver through the common duct from the alimentary canal. This is probably the route of the organism causing suppurative cholangitis, and of that causing the abscess often associated with hydatid cyst of the liver. Finally, regurgitant embolism of the hepatic vein is a possible cause of hepatic abscess. In the vast majority of cases, however, abscess of the liver is preceded by dysentery, whence arises an infectious thrombus, an embolus, or an *ameba coli*.

Morbid Anatomy.—The right lobe of the liver in its thickest part is the most frequent seat of abscess—in two-thirds of all cases. The abscess varies in size from that of a mere point to that of a child's head, the whole right lobe being sometimes converted into one abscess cavity. It may be single or multiple. Rarely, the abscesses intercommunicate. The liver is, of course, proportionately enlarged. Notwithstanding this, the external appearance of the organ may not be changed. On the other hand, if the abscess is near the surface, there may be a prominence under which fluctuation may be recognized, or the liver may become adherent to the abdominal wall or adjacent viscera. The abscess cavity, if of any size, is usually ragged, and not sharply defined from the surrounding hyperemic liver tissue. Such hyperemia may involve two or three rows of acini. In chronic cases, however, there may be a tolerably firm pyogenic membrane.

The contents of the abscess may be pus, or a puriform fluid consisting of the granular débris of cells, oil drops, a few leukocytes, cholesterin and other fat crystals, and numerous crystals of bilirubin. The *ameba coli* has been found among the contents of the abscess, but recognizable liver cells are rarely found. Occasionally the pus may become inspissated, caseous, or even calcified or encysted. Should the abscess accompany hydatid disease, echinococcus hooklets may be found. The contents of such abscesses is generally a true pus. Any form of abscess may perforate the diaphragm and lung, producing interstitial emphysema; or the pus with echinococcus hooklets may be expectorated; or the abscess may burrow into the peritoneum, setting up fatal peritonitis, or into the pericardium, causing fatal pericarditis; into any adjacent hollow organs or into the abdominal wall, discharging externally by fistulous openings.

The thrombotic and embolic forms of abscess always begin as a phlebitis, which rapidly invades the adjacent tissue. Contrary to what is usual in embolism elsewhere, the lodgment of an embolus in the liver is not followed by hemorrhagic infarct.

Symptoms.—There may be latent liver abscess, even when the abscess is of considerable size, though this is a very rare event. Abscess of the liver is generally associated with *pain* in the hepatic region, with *fever*, very often with *chills*, *sweats*, and sometimes with *jaundice*. The pain is almost invariably accompanied with *tenderness*. It may be deep or superficial, and in the latter event it may be sharp and cutting, because involving the peritoneum. The characteristic *shoulder pain* of hepatic disease may also be present.

Fever is, perhaps, the most invariable symptom, and in no other affection of the liver does it rise so high. Indeed, except acute yellow atrophy and the so-called hepatic fever, there are no other diseases of the liver associated with fever. In the former it is of comparatively short duration, and in the latter it is moderate. The temperature reached in abscess is very high,—104° to 105° F. (40° to 40.5° C.)—and may be preceded by chills of corresponding severity, while the fever, in turn, is succeeded by sweats, profuse

and exhausting. Jaundice is not usually present, but may be, when it varies in intensity. When perforation takes place into the pleural sac, it is likely also to perforate the lung, when there succeeds an anchovy-sauce-like expectoration of purulent matter quite characteristic. In this the *ameba coli* may be present.

Physical examination easily recognizes an enlargement of the organ upward in the mammary and midaxillary regions rather than downward, as is usual with other diseases of the liver. Yet the liver is by no means always enlarged, even if there be multiple abscesses. The enlargement is due not merely to the presence of pus, but is also contributed to by the hyperemia and the swelling of cells. The lung being thus encroached upon, the movement of the liver consequent on respiration is less marked than in health. The hepatic region is at first unyielding to palpation, but ultimately fluctuation may be recognized, while a doughy or edematous condition of the abdominal wall is sometimes present and quite characteristic.

Diagnosis.—This may be difficult at first, but as time passes doubts clear up. *Intermittent fever* very naturally is first thought of in many instances, but it will not be long before this disease can be eliminated. There is no enlargement of the spleen, no history of malarial exposure, no malarial organism is found in the blood, and, above all, antiperiodic therapeutics, so efficient in malarial disease, fails of its purpose. In the absence of malaria and in the presence of the causes usually responsible for abscess of the liver there is little else left to mistake for it. A *pleuritic effusion* on the right side gives dullness on percussion in the same locality, but along with this are the diminished fremitus and diminished vocal resonance characteristic of fluid in the pleural sac, while there may also be the bronchial breathing brought on by compressed lung. A *suppurating echinococcus* cyst may give rise to similar symptoms, but in view of its rarity in this country, is scarcely likely to be recognized until aspiration discovers the elements characteristic of it. The needle should be tried early if abscess be suspected, yet it is evident that in so large an organ an abscess of moderate size may easily elude it.

Hepatic intermittent fever, due to chronically impacted calculus, resembles abscess by its fever, chills, and sweats, and by tenderness over the liver, but the history of hepatic colic is present, jaundice is more marked and obstinate, and the condition is evidently not so serious.

Prognosis.—This is generally unfavorable. Even in cases where the abscess happens to point to the surface and is properly opened, death usually supervenes after long and tedious illness, say in six weeks to three months, and, where surgical interference is not possible, death is even more speedy. Cases do, however, recover, not so much by the aid of the physician as through nature's irresistible tendency. It is said that with surgical interference 30 per cent. recover, and where this is impossible 20 per cent. still survive, but this has not been my experience. The hydatid abscess is more apt to terminate favorably if opened than is the infectious abscess.

Treatment.—This is palliative and supporting, except in those cases where surgical interference is possible. The usual measures to relieve pain, nourishing and easily assimilable food, quinin, iron, and stimulants are indicated.

PERIHEPATITIS.

Definition.—An inflammation of the peritoneal covering of the liver.

Etiology.—Perihepatitis occurs in a circumscribed area—(1) as the result of extension by continuity from some one of the various diseases of the liver, such as abscess or hydatid cyst; (2) as a part of a general peritonitis, and (3) rarely by the spread of a pleurisy through the diaphragm; (4) it may also be caused by direct violence, as by a blow, or be the result of a perforation of an ulcer of the stomach or duodenum or gall-bladder.

Morbid Anatomy.—In the more acute forms there is a fibrinous or puriform product with more or less adhesion. These adhesions may lace off areas between the liver and the diaphragm which may be filled with pus, sometimes large quantities, constituting *subphrenic abscess*, or if there be perforation of the diaphragm, *subphrenic pyopneumothorax*, more common over the right lobe. In the more chronic form the capsule of the liver is thickened, especially near the portal fissure, and adhesions may take place with adjacent organs, as the diaphragm, stomach, colon, or abdominal wall. The organ may be shrunken and lobulated, and the portal or hepatic vein and bile-ducts may be stenosed. The capsule of the liver is often found thickened at autopsies when no symptoms were present during life to indicate it.

Symptoms.—The *pain* and *tenderness* which, naturally, are attached to this condition, while often exceedingly severe, like those of peritonitis from other cause, are not distinctive of it. Nor is the *jaundice* resulting from compression of the bile-ducts; nor the symptoms of portal *engorgement* due to compression of the portal vein by the inflammatory products. Physical examination sometimes gives more definite results. Thus, a *friction rub* may sometimes be heard in the mammillary line from the seventh rib downward, and in the axillary line from the ninth rib downward; also sometimes in the epigastrium. It is, however, of short duration. If there is a purulent collection, fever is likely to be present, while the right hypochondrium may be distended and the intercostal spaces motionless. The dullness on percussion may extend as high as the angle of the scapula, and all the signs of a pleuritic effusion may be present. On the other hand, the lower border of the liver may be much lowered—as far down as the navel.

The course of perihepatitis may be acute, or it may be much prolonged, when all the symptoms of chronic suppurative processes are added—fever, high temperature, sweats, fistulous communications with other organs, including the lungs, intestines, and abdominal wall.

Diagnosis.—This lies chiefly between that form of the condition under consideration, attended with pus accumulation between the liver and diaphragm, and an *empyema* or *pneumothorax*. The physical signs and later symptoms are very similar, and it is chiefly in the initial symptoms that the two conditions differ, the one beginning with cough and pleuritic pain associated with cardiac displacement; the other with symptoms more abdominal in situation. The liver in pleuritic effusion and empyema is never so much pushed down as in the hepatic disease. Aspiration may also be availed of in diagnosis. The trocar is to be introduced in the midaxillary line in the seventh or eighth interspace. It was pointed out by Pfuhl that in subphrenic abscess the spurting occurs with inspiration or as the diaphragm moves downward, and in empyema with expiration as the diaphragm moves upward. The atrophic results of perihepatitis are rarely recognized before death.

Prognosis.—This is grave in the severer forms terminating in suppuration. A protracted illness, with gradual exhaustion of the patient's strength, is prone to occur, which skillful surgical measures may nevertheless turn to recovery. Milder attacks terminate favorably in a few days.

Treatment.—Treatment in the early stage must consist of measures to relieve pain, local and general. Counterirritation by cupping operates to check the disease and also shorten the attack. Sinapisms and fomentations contribute in a less degree to the same end. If suppuration occur, the counsel and aid of a surgeon should be early sought, as it is by his efforts that a cure becomes possible.

GLISSONIAN CIRRHOSIS.—This is a term applied to a form of perihepatitis in which the capsule is thickened, assuming a semicartilaginous appearance. It is associated with reduction in size and some degree of interstitial overgrowth and distortion. The capsule may attain a thickness of from 4-10 to 6-10 of an inch (1 to 1.5 cm.).

ACUTE YELLOW ATROPHY OF THE LIVER.

SYNONYMS.—*Icterus gravis; Acute Parenchymatous Hepatitis; Malignant Jaundice.*

Definition.—A rapidly destructive disease of the liver, resulting in fatty degeneration and atrophy of the organ, associated with toxic symptoms and death.

Etiology.—This remarkable and fortunately rare disease is probably due to the action of some virulent poison, autogenetic perhaps, but whose nature is as yet undiscovered. Pregnancy is one of the conditions acknowledged to produce it, and more cases occur among women than men. It occurs in the second half of pregnancy. It has occurred in the course of the infectious diseases, and the usual microbic origin has been held responsible for it, as have been alcoholism and mental excitement. Bacteria have been found in the organ after death. Beyond this we know nothing of its cause.

Pathology and Morbid Anatomy.—The destructive process in the liver is almost identical with that of phosphorus-poisoning, and consists essentially in a very rapid destruction of liver-cells. Opinions are divided as to whether this is the result of an acute inflammatory process, or whether the cells are destroyed by some solvent action. Frerichs and Demme held the view that it is an acute parenchymatous inflammation, of which the chief seat is the peripheral zone of the lobule, whose swelling causes obstruction in the biliary capillaries and the reabsorption of bile. Hensch and von Dusch consider retention of bile the starting-point, and that the liver cells are dissolved by this retained bile. Munk regarded all cases as the result of phosphorus-poisoning.

The liver at necropsy is found very much reduced in size, often to half and even quarter its normal volume. This may take place in three or four days, and even less. A stage of primary enlargement is said to be sometimes present, but is never seen at autopsy. The organ is flattened, flabby, and can be folded over on itself, and the usual lobular markings are either very indistinct or altogether absent. The capsule is loose and wrinkled, and the organ is of a dirty yellow color.

On section, the surface is either uniformly yellow or it exhibits an alternation of yellow and red. The yellow appears, for the most part, in islets, which are surrounded by the red. The yellow represents an earlier stage of the disease. It is soft and spongy, and rises cushion-like above the surface. The red is tougher, more leathery, and sinks below the level of the cut surface. When the organ is uniformly yellow, this later stage, represented by the red, has not been reached before death.

Histologically, the *yellow areas* exhibit softening and apparent solution of the cell network, very few liver cells remaining which retain their own contour. Instead are found disintegrating cells with fat drops of all sizes, the cells being in places still united by their connecting substance so as to maintain the original network. Sometimes crystals of bilirubin, leucin, and tyrosin are met with. The *red areas* consist of a loose connective tissue whose meshes contain fat drops and biliary coloring-matter, representing the softened liver parenchyma bereft of its cells. In places there may be seen a slight degree of cell infiltration of the interstitial tissue, in others irregular branching bands and apparently blind-ending tubes of cells resembling biliary epithelium. These, Waldeyer says, are the result of an attempt at repair. The atrophy usually takes place more rapidly in the left lobe.

The skin and organs are generally intensely bile-stained. There may be small extravasations of blood in various parts. The spleen is enlarged and hyperplastic, the renal epithelium and heart muscle are fatty, while the serous cavities contain more than the normal amount of fluid.

Symptoms.—There are no symptoms distinctive of the beginning of acute yellow atrophy. For several days there may be signs of gastro-intestinal catarrh, promptly followed by jaundice. The former include *headache, malaise, loss of appetite, nausea, vomiting, eructations,* and *epigastric discomfort*. Then there suddenly supervene serious symptoms—*delirium, abdominal pain, convulsions,* local or general *drowsiness,* and *coma*. Sometimes the symptoms of this stage are delayed—in extreme cases as long as three weeks.

The *liver rapidly diminishes in size*. Three or four days may see its disappearance to percussion and palpation, favored by further obscuration by distended air-holding viscera. W. von Leube calls attention to a symptom elicited by palpation which he thinks may be of diagnostic value—a more or less permanent “*pitting*” to pressure in the epigastric region. He ascribes this to an impression made upon the relaxed liver, to which the abdominal wall fits itself. The *spleen*, on the other hand, is enlarged, the *jaundice* is intense, the *vomiting* obstinate, while there may be *epistaxis, hematemesis, hematuria, menorrhagia,* and hemorrhagic extravasations, while the stools are devoid of bile. The pregnant woman aborts. There is little fever, and in the worst stage there is but moderate rise of temperature—rarely above 101° F. (38.2° C.). The pulse, at first infrequent, increases toward the end to 120 or more.

The *changes in the urine* are very characteristic and have been thoroughly studied. It is deeply bile-stained, is concentrated, the specific gravity often reaching 1030. It is slightly albuminous, and may contain the bile acids, bile-stained fatty casts, and bile-stained renal epithelium. The quantity of urea is diminished, even totally absent. The characteristic feature is the presence of *leucin spheres* and *tyrosin needles* in most cases. These crystals may appear without treatment of the urine or they may come down after slight concentration. In addition are found also aromatic oxy-

acids, especially oxymandelic acid, all representing products of albumin disintegration.

Diagnosis.—The symptoms of acute yellow atrophy in the first stage do not admit of a diagnosis. This is the more true because there is no symptom, even atrophy, which may not be wanting. Thus, cases have perished from hemorrhage before the disease was recognized or before jaundice appeared in the rapidly terminating cases. In the second stage, on the other hand, the symptoms are so distinctive that it seems almost impossible for one familiar with them to fail to recognize them. It is, however, so rare a disease in this country that the opportunity does not often present itself; hence it is sometimes overlooked because not suspected, the more excusably because grave nervous symptoms may occur even in catarrhal jaundice and in the infectious diseases—as, for example, in pneumonia, where jaundice is sometimes a symptom. *Acute phosphorus-poisoning* so closely resembles acute yellow atrophy that the diagnosis depends largely upon the possible recognition of the cause. There are, however, some differences. The reduction in size of the liver is not so rapid, the nervous symptoms are not so grave, and leucin and tyrosin are not usually found in the urine of phosphorus-poisoning. *Hypertrophic cirrhosis* also sometimes resembles acute yellow atrophy clinically, but the enlarged liver is the distinctive feature of the former.

Prognosis.—This is so unfavorable that recovery may be said to imply an error of diagnosis.

Treatment.—There is no curative treatment. Symptoms should be relieved by the usual palliatives. Headache should be relieved by phenacetin and acetanilid, rather than morphin. An ice-bag may give great relief.

MORBID GROWTHS OF THE LIVER.

The only morbid growths of the liver which are of clinical importance are *cancer* and *sarcoma*. An *angioma* is an interesting new formation of small size, which presents no recognizable symptoms before death. It is composed of vascular tissue and is distinctly capsulated. The large sizes may be as large as a walnut, more rarely still larger. Some pathologists describe an *adenoma*, which others class among the cancers as a trabecular variety. *Myoma* is another form of histioid tumor rarely found in the liver. *Cysts*, represented by the dilatation cyst and the hydatid cyst, are of occasional occurrence.

CARCINOMA OF THE LIVER.

Etiology.—Cancer of the liver is a comparatively common disease; of internal organs, next in frequency to that of the uterus and stomach. It is, moreover, in the vast majority of cases secondary—in full three-fourths of cases, and of these two-thirds are secondary to primary cancer of the portal area, one-third to primary cancer elsewhere. The stomach is, naturally, the most frequent primary focus. Cancer of the liver is most common in male adults between the fortieth and sixtieth year, yet it does occur occasionally in children.

Morbid Anatomy.—There are two chief forms in which cancer of the liver presents itself—the *nodular* and the *massive*. Rare forms are radiating, colloid, and cancer with cirrhosis.

1. In the *nodular form* nodules of various sizes are scattered throughout the organ. The nodules vary in diameter from one-fifth of an inch to two inches (0.5 cm. to 5 cm.) or more. They are usually opaque, white, or yellowish-white, and may be very numerous. The superficial nodules project above the surface, and may even be felt through the abdominal wall in the emaciated subject, giving rise to the oft-described "bosselated" feel. These superficial nodules are often umbilicated, because of the disintegration and absorption of the older central cells, leaving a residue of connective tissue and partially-obiterated blood-vessels. The umbilication is confined to the superficial nodules, which also received the name of Farre's tubercles. This variety of nodular cancer may be both primary and secondary. The nodules usually reach a larger size in the secondary, and are apt to be more numerous.

2. The *massive form*, in which there is one large cancerous mass, greatly increasing the bulk of the organ. It is grayish-white in color, and may reach four or six inches (10 or 15 cm.) in diameter. This form is primary.

3. The *radiating form*, usually pigmented, in which the nodules may also be multiple, but smaller and less numerous than in the nodular form. It is a form of secondary cancer.

4. A *colloid form*, rare and only secondary.

5. A rare form is *cancer with cirrhosis*, in which the liver is but slightly enlarged, weighing 4.5 to 6.5 pounds (*circa* 2 or 3 kilograms), and presents a greenish-yellow appearance, studded over with *small white nodules* not unlike those of the hob-nail liver, the same appearing in large numbers when the organ is cut.

All varieties of cancer are subject to *degeneration*, but the secondary forms more rapidly. The change is a fatty metamorphosis of the cells, associated sometimes with rupture of blood-vessels and large extravasations of blood, which may even burst into the peritoneum and gall-bladder. There may be occasional *suppuration* around the nodule.

As to the histological origin of cancer, the primary forms start in the liver cells; they are true epitheliomata, the capillary network forming the primary stroma, to which an independent growth of stroma is subsequently added. The secondary forms are embolic in origin, chiefly through the branches of the portal vein, but possibly by the hepatic artery, with or without intermediate involvement of the lung, the first new cancer cell being an infected cell of the capillary wall, whence the parenchymal liver cells are in turn affected. The stamp of the pigmented radiating cancer is, perhaps, thus derived, and illustrates this mode of invasion. The secondary forms repeat the type of the primary varieties. The cells are mainly epithelioid, but may be polygonal and even cylindrical. They exhibit various grades of fatty degeneration.

The liver is variously enlarged by these different forms of cancer, the maximum product being the largest produced by any disease of the liver (see Fig. 36).

SARCOMA.—Of the remaining morbid growths of the liver, sarcoma alone demands a few words. It is almost invariably secondary, very few cases of primary sarcoma of the liver having ever been found. Secondary sarcoma of the liver includes melanosarcoma, lymphosarcoma, and myxosarcoma. The melanosarcoma is the most frequent and interesting. It is always secondary and usually multiple, though a diffusely infiltrated variety

exists, giving the liver on section a granitic appearance. Melanotic sarcoma of the orbit often precedes it, and it is sometimes a part of a general melanotic distribution over the body, including the skin. *Sarcoma of the liver is said to be never associated with ascites.*

Symptoms.—Very rarely cancer of the liver may be latent, except as to a vague ill health explained by the findings of the autopsy. In most instances such ill health grows worse more or less rapidly, and examination of the liver discovers *enlargement*, to which may or may not be added recognizable *nodules*. The enlargement may extend beyond the umbilicus,

Fig. 36.—Showing Approximate Enlargement of the Liver Corresponding to the Different Diseases Described in the Text—(after Rindfleisch).

- I.* Position of the diaphragm to the maximum enlargement (carcinoma and in abscess).
II, II. Normal situation of the diaphragm. *II, III.* Relative dullness. *IV.* Border of the liver in cirrhosis. *V.* Border in health. *VI.* Lower border of the fatty liver. *VII.* Of the amyloid liver. *VIII.* Of cancer, leukemia, and adenoma.

but it is not usually so great, and in some cases there is none whatever. To inspection the enlargement is first seen in the upper zone of the abdomen, and produces a change of configuration which involves commonly the whole upper abdomen. Rarely, the nodules may be seen. The *superficial veins* are enlarged.

The other signs of ill health alluded to, apart from those of a primary cancer elsewhere, are *loss of appetite*, *nausea*, a *sense of epigastric fullness*, *pain* in the epigastric or hypochondriac region or in both simultaneously. The pain may be lancinating and extend to the right shoulder. To this

tenderness is sooner or later added. Indeed, perhaps tenderness precedes. *Emaciation* may have preceded the more striking degree of these symptoms and increases rapidly, while the characteristic *cachexia* develops *pari passu*. An examination of the blood shows a *reduction of hemoglobin and corpuscles*, and as the blood becomes thin *edema* develops. In some cases there is *fever*, especially toward the end, with a temperature of 100° to 102° F. (37.8° to 38.9° C.), more or less intermittent, but rarely associated with rigors.

Obstructive *jaundice* is a frequent symptom in *carcinoma hepatis*—it may be said in fully half the cases. It is due to compression of the smaller biliary passages, and does not usually reach a high degree. Nor are the feces usually devoid of bile. If the latter event occurs, and the jaundice is intense, it means that some of the larger ducts are obstructed, while involvement of the gall-bladder or the portal lymphatics may be suspected. *Jaundiced urine* is about as constant as jaundice itself. The presence of melanin is said to point especially to the presence of the pigmented varieties of cancer. Albuminuria is, on the other hand, unusual.

Ascites is a rather infrequent symptom, and can only occur when the portal vein or branches become involved either by compression or invasion. Should, however, a bloody fluid be obtained by tapping, and a tumor of the liver be present, the indications are that the tumor is cancer. *Enlargement of the spleen is rarely present* in cancer of the liver.

The duration of the disease ranges from *three to fifteen months*.

Diagnosis.—This is not always easy, even if there is enlargement. It is simplified if the nodules can be felt, or if there is recognized primary cancer elsewhere.

The smooth, enlarged liver of cancer is distinguished from that of the more benignant conditions of fatty liver and amyloid liver by the absence in these two of grave symptoms and of jaundice. The *fatty liver* is softer than the liver of cancer, the *amyloid* is harder, more often smoother, while its rounded border can sometimes be felt. It is also accompanied by enlarged spleen. In *abscess* of the liver the organ may be soft or doughy in consistence, and the same may be true of the abdominal walls over it. There are also the causes of abscess of the liver, and among symptoms the characteristic chills, high fever, and sweats.

Multiple *echinococcus cysts* may furnish similar local signs, even the "bosselated" feel, but hydatid disease is rare in temperate climes; the nodules are softer, the disease is of longer duration, and is less rapidly followed by wasting. Enlargement of the spleen is quite common in hydatid disease, present, it is said, in nine-tenths of all cases. Jaundice is even more frequent in this disease than in cancer—in four-fifths, as contrasted with a little more than one-half. Aspiration may aid in the solution. Of other affections attended by uneven surface of the liver the *amyloid organ beset with gummy nodules* offers difficulties, but the lesser gravity, the longer duration, and, especially, the syphilitic history solve the question. Cancer, as a rule, is not associated with enlarged spleen, but the rapid enlargement of the liver in amyloid disease sometimes obscures the enlarged spleen and even interferes with its development.

Doubt sometimes arises in the presence of *certain stubborn forms of jaundice* as to whether cancer may not be the cause, especially as in some of these there is rather rapid loss of weight. If there is enlargement of the liver, the solution is less difficult, because in simple jaundice

there is no enlargement; but in its absence time alone can settle the question; for stubborn as these rare cases of jaundice are, they are less so than cancer, while even if they are not followed by ultimate recovery, their course is much longer than that of cancer. Should ascites arise, the question is settled in favor of cancer. It may sometimes be difficult to decide between cancer and *hypertrophic cirrhosis*, which also furnishes an enlarged, hard, more rarely nodular liver, with jaundice. Carcinoma occurs in persons over forty years of age, hypertrophic cirrhosis in those younger. Carcinoma produces cachexia, hypertrophic cirrhosis does not. Carcinoma produces marked tenderness, hypertrophic cirrhosis but slight. A possible cause in either case must be sought, primary cancer elsewhere pointing to cancer, and the alcoholic habit to cirrhosis, to which also the enlarged spleen and the absence of cachexia point. A family history of cancer, if present, adds weight to other signs of cancer of the liver.

There is no special reason why cancer of the liver should be distinguished from *sarcoma* or *adenoma*, as the clinical significance of the various conditions is about the same. But if, along with a primary sarcoma elsewhere, as in the orbit, there appears enlargement of the liver, then the inference is reasonable that a secondary sarcoma is there established. Melanosarcoma is more likely to invade other organs, as the lungs, kidneys, spleen, and even the skin.

There is no evidence by which secondary cancer can be distinguished from primary, except by the presence of primary cancer elsewhere, notably in the stomach, breast, large intestine, uterus and appendages, and the presumption based on the fact that the majority of all cases of cancer of the liver are secondary. Careful search should, however, be made for cancer in all organs in which primary cancer is likely to occur. The gastric secretion should be investigated chemically, the rectum explored by the finger and speculum, the uterus by the finger, speculum, and sound. Such investigation is further useful in the settlement of the diagnosis of cancer of the liver, for a doubtful case becomes confirmed if a primary focus can be found.

Prognosis.—This disease is invariably fatal—usually in from three to fifteen months.

Treatment.—This must consist in attempts to relieve the discomfort and prolong the life of the patient.

SYPHILIS OF THE LIVER.

Definition.—Syphilis of the liver includes several morbid conditions due to this specific poison, which are best considered under a single title.

Etiology.—Syphilis of the liver may be the result of acquired or inherited syphilis.

Morbid Anatomy.—1. The product in the liver of *inherited* syphilis is always a cellular infiltrate, which may be diffuse or localized. (1) The diffuse infiltrate produces an enlargement and hardening of the organ, which gives place to a reduction in size and unevenness due to contraction of the newly-formed connective tissue. (2) The circumscribed product, more rare as the result of inherited syphilis, is the gummy tumor. The gummy tumor is rather a product of acquired syphilis, but rarely also it is found in connection with hereditary syphilis.

2. The changes in the liver due to *acquired* syphilis are regarded as

one of its tertiary manifestations, and do not show themselves until some time after the primary infection—it may not be for several years. They are represented by the syphilitic gumma or syphiloma, by an interstitial hepatitis, by amyloid disease, and occasionally by endarteritis.

(1) Diffuse interstitial hepatitis does not differ essentially from the more usual forms of non-specific cirrhosis. The ultimate product is sometimes very irregular, and the lobules preserve a palpable distinctness. (2) The gumma is the most characteristic lesion of tertiary syphilis. It is a nodular growth, which may be as small as a pea or smaller, or as large as an orange—from 1.5 to 4 inches (5 millimeters to 10 centimeters) in diameter. A favorite seat is the convexity of the organ near the suspensory ligament; another, on the under surface in the connective tissue embracing the portal vessels; while it is also found in the substance of the organ. The tendency is to cheesy change in the center of the nodule, and to contraction, which distorts the liver and reduces its size, with the formation of cicatricial markings and furrows. These cicatrix-like puckering and fibrous bands are found also on section of the syphilitic liver. (3) Amyloid disease has been considered. (4) Endarteritis sometimes invades the smaller, and even the larger, branches of the hepatic artery and portal vein.

Symptoms.—Syphilitic changes in the liver are often first discovered at autopsy. When symptoms are produced during life, they are commonly those due to portal obstruction, as already detailed in treating ordinary cirrhosis. *Jaundice* is not a frequent symptom, yet it was early made a matter of record. Thus, Paracelsus (1789) is said to have noted the complication of syphilis with jaundice, which could not be cured until the venereal disorder was overcome. Portal (1813) also speaks of jaundice as one of the evils following syphilis, curable only by the use of mercury. Ricord (1851) noted two cases of jaundice complicated by syphilis; but Gubler (1854) first pointed out that jaundice commonly comes on at the beginning of the secondary stage, and also treated of the relations of jaundice to the general infective process. He collected seven cases in which jaundice followed syphilitic infection. It accompanied a syphilitic exanthem, and was also preceded by *digestive disorders, loss of appetite, nausea, diarrhea, bitter taste in the mouth, and pain in the epigastrium*. I have recently had under my care one case precisely fulfilling these conditions pointed out by Gubler. The jaundice may be slight, moderate, or severe. It rapidly attains its maximum intensity, lasting a variable time, seldom more than a fortnight. Though the explanation may not be immediately easy, Gubler gives sufficient reasons for justifying a relation of cause and effect. It is possible that the poison may act like certain other poisons which produce grave icterus, as phosphorus. On the other hand, it is quite as likely that it may arise from a duodenal and biliary catarrh, the result of the general disturbance, especially as it is so often associated with other symptoms of this condition—viz., loss of appetite and nausea.

Enlargement of the spleen is an associated symptom when there is amyloid disease, to which ascites may also be added. Sometimes the larger nodules of gummy growth can be felt through the abdominal walls, when the diagnosis must be made between syphilis of the liver and carcinoma, a differentiation greatly aided by the history of the case.

Diagnosis.—This depends most largely upon the history of the case, which must be carefully sought. Nor should the physician be satisfied

with a negative history, in view of the fact that it is so common for syphilitic subjects to deny infection, even though they know it is to their interest to tell the truth. Careful examination should, therefore, be made for secondary symptoms, such as glandular enlargement or cicatrices and markings left by syphilids.

Prognosis and Treatment.—Patients should be subjected to the usual syphilitic treatment by iodid of potassium and bichlorid of mercury as soon as the diagnosis is established, and even when it is doubtful. For while early treatment may be efficient in preventing new growths, it is less certain that when present they can be removed by antisyphilitic treatment.

PARASITES OF THE LIVER.

ECHINOCOCCUS DISEASE, OR HYDATID CYST OF THE LIVER.

Etiology and Pathogenesis.—The most important of the parasitic diseases of the liver is the echinococcus or hydatid disease, due to an invasion by the embryo or larva of the *tenia echinococcus*, a minute tape-worm, consisting of three or four links, and about 1-5 inch (4 to 5 mm.) long, whose natural habitat is the upper part of the intestine of the dog. It has been found, also, in the wolf and jackal. The worm is not often found in this country. This rarity may, however, be more apparent than real, as the parasites are so minute (see Fig. 37) as to be easily overlooked, forming, as they do, minute, thread-like bodies, adhering to the villi of the intestine, while hydatid disease, though not very common, is still, nevertheless, more so than would be expected from the rarity of the worm. There are few hospital physicians of much experience who have not met one or more cases, though they are most common in foreigners. In Australia and Iceland, where the intercourse between men and dogs is more intimate, it is a comparatively common disease. In the latter country 28 per cent. of all dogs are said to be infected; in Copenhagen, 4 per cent.; in Zurich, 3.9 per cent.; in Lyons, 7.1 per cent.; in Berlin, 1 per cent.; and in Leipzig, none, as far as investigated.

The ovum, entering the human intestine with food or drink, has its egg-shell dissolved off by the digestive fluids; the larva is liberated, and bores its way by its stilettos and hooklets into a branch of the portal vein, through which it is carried to the liver. Lodging there, the hooklets disappear, and the embryo becomes a small cyst, possessed of two layers—an external cuticle of laminated structure, the ectocyst, and an internal parenchymatous or germinal layer, the endocyst. Within the cyst is a clear fluid. Surrounding the cyst is gradually developed a capsule of connective tissue, due to reactive inflammation.

At the earliest stage at which these bladders or resting embryos have been with certainty observed,—by Leuckart in the pig four weeks after feeding with ripe proglottides,—they form solid, spherical bodies, 25-100 to 35-100 of a millimeter in diameter, resembling a mammalian egg, and which are subsequently differentiated into the bladders.

Development from Proscolex.—When from fifteen to twenty millimeters in diameter this proscolex, or bladder-worm, proceeds to the development of numerous heads or scolices. It may give rise, first, to a single head, producing a *cysticercus*; second, to many heads, each of which is termed a

cenurus; third, to many heads produced, not directly from the germinal layer, but indirectly from special delicate sacs called *brood capsules*, which arise as minute elevations from the cells of the germinal layer. In these elevations a small spheroidal cavity appears, gradually increases in size, and becomes lined internally with a delicate cuticular membrane, outside of which is a layer of cellular structure. Thus, the wall of the brood capsule consists of two layers like those of the mother bladder, but inverted as to relative position, as if the brood capsule were an invagination of the mother bladder. These brood capsules exhibit active movements.* From the internal wall of the brood capsule arises the head, first as a discoidal thicken-

Fig. 37.—*Tænia Echinococcus*, from the Dog—(after Heller).
At *a*, natural size; at *b*, magnified.

ing, growing into an externally situated club-shaped process, perforated longitudinally by a tube-like continuation of the cavity. While an external protrusion of the brood capsule, it may be temporarily inverted. At the distal end of this protrusion, furthest from the point of attachment, the suckers and hooks of the head or scolex are formed. The hooklets appear as a thick fringe of prickles, all of which, except the foremost rows, subsequently drop off. Thus, in different stages of development, heads to the number of ten, fifteen, or twenty may live within one capsule, and in large bladders the included capsules may number thousands. From these, on arriving in the intestine of a suitable host, the proglottides of the strobile,

* They are easily ruptured and may escape observation altogether, whence it has been inferred that connection between the heads and brood capsules is temporary, and that, after separation, the living scolices float free in the fluid of the mother bladder. According to Leuckart, however, all parts of the echinococcus—mother bladder, brood capsules, and heads—are throughout life in direct continuity with one another. According to Verco and Stirling, it may be that the scolices are also formed directly from the germinal membrane, in evidence of which they state that they have examined a specimen which shows four heads sprouting directly from the germinal membrane of an exogenously developed daughter cyst.

or sexual worm, are formed by lengthening and transverse segmentation. The period of development from the scolex condition to that of the adult worm varies from four to eight weeks.

The hydatid bladder thus described consists of a single sac, which may attain an enormous size, bearing on its surface brood capsules containing scolices in varying number and stages of development. This is the form of cyst known as *echinococcus veterinorum*, because common in the domestic animals, though frequently also found in man.*

Development by Daughter Cysts.—In another method of development secondary and completely separated bladders may be formed, either inside or outside the primary or mother cyst, constituting daughter cysts. The former, or endogenous type, is that usually met in man,—*echinococcus hydatidosus* of Leuckart, *echinococcus endogenus* of Kuhn,—and arises either by vesicular transformation of the scolices of the brood capsules, or by infoldings of the parenchymal layer. The daughter cysts thus formed and lying within the parent cyst, with which they correspond in structure and behavior, also give rise to brood capsules and scolices. These daughter bladders may also bud endogenously and exogenously, and produce a third or fourth generation within or without themselves, the whole brood being contained within the mother bladder.

Fig. 38.—Section through an Echinococcus Cyst with Brood Capsules—(from Braun, after Wax Model).

The exogenous type—*echinococcus exogenus* of Kuhn—is less common in man, but is frequently met in domestic animals, especially the pig. In this form the secondary bladders arise from small granular masses in the deeper layers of the cuticle of the mother cyst, probably ultimately derived from the parenchymal layer. They assume a special cuticular covering, and their central parts clear up and liquefy. As the centripetal formation of new layers in the cuticle of the mother bladder goes on, with rupture of the outer layers, the new formations make their way externally as separate sacs, and undergo subsequent development outside of the mother bladder, usually close to it, though at times, as in hydatids of bone, the individuals of the resulting broods may lie at some distance from one another and from their common parent. It is to a special variety of this latter that Virchow has given the name *echinococcus multilocularis*, wherein the cysts, becoming surrounded and joined together by thick capsules of connective tissue, form a hard tumor composed of vesicles the size of a pea, often resembling, *en masse*, colloid cancer. In the spaces are found remnants of the echinococcus cyst, at times hooklets or scolices, by the discovery of which their true nature is determined. At other times they are barren. Most cases of this form of disease have been met in Bavaria and Switzerland, but one case

* J. C. Verco and E. C. Stirling in Allbutt's "System of Medicine," vol. ii., 1897, p. 1110.

being reported in this country—by Delafield and Prudden, in their "Pathological Anatomy," third edition, page 372. The subject was, however, a German, who had been in the country five years.

The *fluid contents* of the young cyst are clear and limpid, have a specific gravity of 1005 to 1009, are non-albuminous, but contain a small quantity of chlorid of sodium, occasionally a trace of sugar, succinic acid, or hematoïdin. Scolices and hooklets are almost always present, and are of great diagnostic value.

The hydatid cyst ranges in size from that of a pin's head to a child's head. It grows very slowly, and may be in the liver for many years—some say as many as twenty. Ultimately it dies, the walls contract, their contents become inspissated and calcified. The walls also become calcified. Sometimes they suppurate, the cysts forming large abscesses; or they may rupture in various directions with corresponding mischief, including sudden death from collapse. The bile passages and inferior cava have been seats of rupture.

Symptoms.—Small cysts may occasion no symptoms, being often unexpectedly found at necropsy, and under any circumstances the failure of health is very gradual at first. As cysts become large they produce a *sense of weight or dragging* in the region of the liver, and other symptoms, depending on their size and situation; *jaundice*, if they cause obstruction of the biliary passages; *dyspnea* and *cardiac disturbance*, if they encroach on the lungs or heart; *pyemic symptoms*,—that is, fever, sweat, and sometimes chills, with rapid exhaustion,—if they suppurate. The liver may become very much enlarged, demonstrable by inspection, palpation, and percussion. If there is a single superficial cyst, either in the right or left lobe, it may be felt as an elastic or even fluctuating tumor; or there may be the distinct feel of a nodular growth over the liver. If posterior in the right lobe, it may encroach on the inferior part of the lung and pleural space, causing dullness on percussion posteriorly and postero-laterally, and other signs of pleuritic effusion. *Hydatid thrill* or *fremitus* is always to be sought for. It may be found, if the cyst is superficial, by placing one hand over the tumor and tapping lightly with the fingers of the other. The result is a vibrating or trembling movement felt for a short time. It is not often obtainable, and is possible only with superficial cysts. It has been ascribed by Briçon to the collision of the daughter cysts.

If rupture occurs, other symptoms are added. The pleural cavity is often invaded, or the lungs, as evidenced by the expectoration of cysts and hooklets; the bile passages, by the production of jaundice or increased jaundice, and the subsequent appearance of hooklets and cysts in the fecal discharges. Rupture into the stomach is manifested by vomiting of hooklets and cysts; into the vena cava, by embarrassment of right cardiac action and pulmonary thrombosis from lodgment of cysts; into the pericardium, by fatal pericarditis; into the peritoneum, by fatal peritonitis; and into the abdominal wall, by outward discharge.

Diagnosis.—The differential diagnosis depends on the recognition of hydatid fremitus or on some of the pathognomonic features just mentioned, and the history of the case in connection with the slowness of development of the symptoms. The resemblance to *cancer* is sometimes very close, in consequence of the presence of nodular swellings over the liver, and to *syphilis of the liver* for the same reason. In cancer the health fails very much more rapidly, but in syphilis scarcely more so, and the history must here again come

to our assistance. When suppuration takes place, we have the symptoms of *abscess* of the liver. The recognition of sugar in the fluid obtained by tapping is presumptive evidence of its hydatid nature.

Prognosis.—When the disease develops sufficiently to manifest symptoms, the chance of spontaneous recovery is very slight. It is possible when external rupture takes place, but this should be anticipated by operative interference, which is often successful.

Treatment.—No medicinal treatment avails, while spontaneous cure is not infrequent, by reason of the death of the parasite before the development of the disease to a recognizable degree. A surgeon should be consulted as soon as the diagnosis is made. A preliminary tapping is justified under strict antiseptic precautions, and, in fact, has been succeeded by permanent recovery. Australian surgeons have had the largest experience, and it appears to justify the bolder course of incision and evacuation of the cysts rather than the more conservative method of first securing adhesion of the sac to the abdominal walls and then laying open the cyst and evacuating the contents. The former practice of injecting the sac with iodine has also been discontinued. Should suppuration take place, the treatment becomes that of abscess of the liver.

OTHER PARASITES OF THE LIVER.

The remaining parasites of the liver are of pathological rather than of clinical interest.

The arthropoda are represented by the *pentastomes*, of which the *pentastomum denticulatum*—larval form of the *pentastomum* or *linguacula tenioides*—has been found in the liver. The adult worm is lancet-shaped and marked with numerous rings. The female is from three to five inches (8 to 13 cm.) long, the male little less than one inch (1.8 to 2.5 cm.). The adult worm has been found in the nostril of man.

The *cystercus cellulosa* and *psorosperma* are rare parasites. Of the latter, the *coccidium oviforme*, which is very common in the liver of the rabbit, produces whitish nodules, as in other organs, ranging in size from that of a pin to that of a split pea, and even larger. They may produce fever of an intermittent type, diarrhea, nausea, and tenderness over the liver or other organ invaded with enlargement. (See also Parasites at end of volume.)

In examining a case of suspected hepatic disease the following questions should be raised with a view to eliciting important facts which bear upon the diagnosis: First, whether there has been or is syphilis; second, suppurative disease or rickets; third, alcoholism; fourth, enlargement of the spleen; fifth, elevation of temperature; sixth, jaundice; seventh, what has been the duration of the symptoms?

DISEASES OF THE PANCREAS.

Almost the only disease of the pancreas which possesses much clinical interest is cancer. It is true that Reginald H. Fitz has invested the subject of pancreatitis with increased interest by his masterly Middleton Goldsmith lecture, but I note that few cases more are now recognized antemortem than previous to its publication. The remaining diseases are, however, of great pathological interest.

ACUTE PANCREATITIS.

Definition.—Acute pancreatitis is an acute inflammation, affecting primarily the fibrous and fatty interstitial tissue of the organ. It is a rare affection. Fitz divides it into hemorrhagic, suppurative, and gangrenous, but as suppuration and gangrene are rather terminations than initial features, and hemorrhage is at least a very frequent primary etiological feature, I prefer to treat the subject under the single heading of *acute pancreatitis*.

Etiology.—It may begin with hemorrhage, which may be traumatic. Most subjects are between twenty-six and seventy years old. The majority are men. A few are alcoholics. James M. Anders* collected 40 cases of pancreatic hemorrhage, in 34 of whom the sex was given. Twenty-five of these were males and 9 females. The ages of 30 were stated, of whom 13, or 43.3 per cent., were over forty-five. Many have been previously subject to gastric and gastro-intestinal derangements, often inflammatory. The causative gastroduodenitis extends probably from the bowel to the pancreatic duct.

Morbid Anatomy.—This varies with the stages or varieties, which, as seen at necropsy, are *hemorrhagic*, *gangrenous*, and *suppurative*. In the *hemorrhagic* stage the pancreas is enlarged throughout or at its head, and is infiltrated with blood, which imparts its color in different shades and may invade the pancreatic duct. The hemorrhagic foci may alternate with white spots of fat-necrosis. The hemorrhage may extend into the peri-pancreatic tissue or the mesentery, mesocolon, omentum, and beyond to the brim of the pelvis. On minute examination round cells and red blood discs are found in the ducts and acini. Many lobules are in a state of coagulation-necrosis, while bacteria are present in large numbers.

If the patient survive the first few days,—say the fourth day,—the condition passes on either to *gangrene* or *suppuration*. If to *gangrene*, the tip or the entire gland may be converted into an offensive, dark, slate-colored mass, which softens and becomes shreddy. Gangrene may set in almost simultaneously with hemorrhage. The organ may become completely sequestered in the smaller omental cavity, attached only by a few shreds. The adjacent parts exhibit the appearance of peritonitis, with dirty, purulent extravasate. Disseminated fat-necrosis may be present. The spleen may be enlarged and its veins thrombosed, as may be also the portal vein.

In the *suppurative* termination the organ is enlarged, and contains numerous small abscesses, intervening parts being hyperemic. There may be peritonitis of adjacent areas of the peritoneum. There may be diffuse suppuration or small abscesses disseminated throughout the organ. In the chronic form there may be a solitary abscess as large as a hen's egg, with cheesy contents. The lesser omental cavity and peripancreatic tissue may be invaded; rarely, also, the liver. Fat-necrosis in this form is a rare condition, while thrombosis of the splenic and portal veins may still occur.

Symptoms.—The disease begins suddenly with *abdominal pain*, sometimes succeeding attacks of indigestion. It is severe and in the upper left quadrant of the abdomen and in the course of the pancreas, but it may extend throughout the abdomen. It is ascribed to stretching of the celiac plexus of nerves. There is also tenderness. The pain is usually followed by *vomit-*

* "Pancreatic Hemorrhage," "Journal of the American Med. Assoc.," December 2, 1899.

ing, rarely by nausea alone. The vomited matter may be bilious or black. The upper abdomen becomes swollen and tympanitic, or the *tympany* may be general. The *temperature* is *subnormal* or *slightly elevated*. Death occurs usually within three days, but may be delayed a week. If the patient lives longer, the case becomes one of gangrenous pancreatitis. Recovery may occur, though rarely.

If the gangrenous termination succeeds, *chills*, *fever*, abdominal *swelling*, generally *tympanites*, *tenderness*, *jaundice*, collapse, and death are added.

If suppuration ensues, life may be prolonged for three or four weeks, and there may be added *high temperature* and *irregular chills*, with exacerbations and remissions and signs of deep-seated peritonitis in the epigastric region.

Diagnosis.—This is based upon the foregoing symptoms and their suddenness, especially the circumscribed tympany. The disease is to be differentiated from the effects of *irritant poison*, *perforation of the stomach* or *biliary tract*, and *acute intestinal obstruction*. The history eliminates corrosive poison. Perforation of the stomach is preceded by symptoms of ulcer, and of the biliary passages by symptoms of gall-stones. There is no tenderness localized in the region of the pancreas in intestinal obstruction, which is rare in the upper part of the small intestine. Obstruction in the large intestine must be eliminated by measures calculated to determine the patulousness of the bowel. Laparotomy has been done for intestinal obstruction, and pancreatitis was found.

Prognosis and Treatment.—The former is almost always unfavorable. If recovery takes place, it is accidental rather than the result of treatment, which, in the main, can only be palliative, and such as is demanded by peritonitis. Surgical treatment may be called for, and has been followed by recovery. Drainage should be practiced.

CHRONIC PANCREATITIS.—This consists of an interstitial overgrowth, by which the organ is hardened and slightly enlarged. The secreting structure is compressed and degenerated. It has frequently been found in diabetes. There may be pigmentary deposits, and pancreatic calculi may be found in the ducts.

CANCER OF THE PANCREAS.

Morbid Anatomy.—Though a rare disease, it is not infrequently correctly diagnosed. It is usually primary and situated in the head of the organ. It is commonly scirrhus, but it may also be colloid. It is especially apt to invade adjacent parts by contiguity, and more distant ones by metastasis, especially the liver and lymph glands. It may arise by contiguity from cancer of the stomach or intestines. It occurs in those past middle life.

Symptoms.—These are not distinctive. The most valuable symptom is *jaundice*, which occurs when the head of the organ is involved. It is caused by obstruction of the common bile-duct. A *fixed tumor* may be felt in the pancreatic region, and if it be associated with jaundice, the pancreas may be justly suspected to be its seat. If we add to these symptoms *fatty* or *greasy stools*, the suspicion is fortified. There are symptoms of *indigestion* and a *dull pain* in the epigastrium, but these are not distinctive. *Emaciation* and *loss of strength* proceed irresistibly. As the former advances the *aortic pulse*

is transmitted with great distinctness through the transverse colon and pancreas. There may be *ascites* and *diabetes mellitus*.

Diagnosis.—Cancer of the pancreas must be differentiated from cancer of the pylorus, of the transverse colon, of the glands in the hilus of the liver, and from aortic aneurysm. In case of *cancer of the pylorus* there should not be much difficulty, for the pyloric tumor is movable in a decided majority of cases, and the pancreatic is fixed; the pyloric cancer is rarely associated with jaundice, the pancreatic is almost always so; pyloric cancer produces dilatation of the stomach, pancreatic cancer does not.

Cancer of the transverse colon is rare. It is also more movable than pancreatic cancer, and sooner or later obstruction of the bowel results. *Cancer in the hepatic fissure* is difficult to distinguish, but it is higher up and more superficial. The tumor is also tender. Both are accompanied by jaundice.

The pulsation communicated to the pancreas is very different from the expansile dilatation of *aneurysm*. Fatty stools are of great assistance in diagnosis, but they are by no means always present.

Sarcoma is a possible tumor of the pancreas, but it is not distinguishable from cancer, tuberculosis, and syphiloma.

The **prognosis** is unfavorable, and the **treatment** only symptomatic.

CYSTS OF THE PANCREAS.

Definition.—These are retention cysts, due to closure of Wirsung's duct by concretions or cicatricial contraction. They may become very large, and may even occupy the entire abdominal cavity. They may be slow or rapid in development.

Symptoms.—In none of the 53 cases thus far collected—35 by W. W. Johnston and 18 by N. Senn—was there fatty diarrhea, a condition regarded as symptomatic of suspended function of the pancreas. On the other hand, the *stools* may be *clay-colored* and *putrescent*, probably because there is a simultaneous obstruction to the descent of bile. A resulting *tumor* presents itself usually in the left part of the epigastrium, between the costal cartilages and the median line. More rarely it is in the neighborhood of the navel. It is globular, resisting, and inelastic, changes its position slightly with the movements of the diaphragm, and possesses some lateral motion.

The differentiation of such a tumor, in the absence of more definite symptoms, cannot be said to be easy, yet the diagnosis was made in seven out of Senn's eighteen cases. Aspiration should be made. The fluid is usually brown or chocolate-colored, but sometimes it is transparent. It presents some of the characteristics of pancreatic fluid, emulsifying fats and converting starch into sugar.

Treatment.—After exploratory aspiration the treatment is surgical.

PANCREATIC CALCULI.

History.—The first case of pancreatic lithiasis reported, so far as I know, was in 1788 by Thomas Cawley. There was diabetes, and at necropsy the pancreas was found stuffed with calculi. In 1882 I made a necropsy on a case of diabetes with diarrhea, in which many calculi were found in the pancreas. In 1883 George W. Johnston reported 35 cases collected from the literature. Minnich reported a case of colic after which calculi composed of calcic carbonate and phosphate were found in the stools; Lichtheim made the diagnosis of pancreatic calculus in a case of severe colic, diabetes, and fatty diarrhea, confirmed by autopsy. Out of 1500 autopsies made at the Johns Hopkins Hospital up to 1901, only two cases of pancreatic calculus were found.

Etiology.—Pancreatic calculi can only be regarded as a precipitation from an inspissated pancreatic juice determined by some unknown cause.

Morbid Anatomy.—The calculi, commonly about as large as a pea, are contained in the pancreatic duct and its branches. They are usually numerous. They may be smooth, round, faceted, or irregular and rough of surface. They are composed of carbonate and phosphate of lime.

Symptoms.—Pancreatic calculi are often unattended by symptoms, but deep-seated colicky pain may be present. The difficulty in distinguishing this from the pain of biliary colic is increased by the fact that jaundice may be associated with either. Theoretically, the pain of pancreatic colic should be more deep-seated, more central, and more to the left. Practically this is not often found to be the case. If fatty diarrhea and diabetes are associated with the colic, pancreatic calculus may be inferred. Rarely stones are passed by the bowel, and if such stones are found to be made up of phosphate and carbonate of lime, they probably come from the pancreas.

Treatment is mainly palliative by morphin or other anodynes. Eichhorst has recommended hypodermic injections of pilocarpin to stimulate the pancreatic secretion.

DISEASES OF THE SPLEEN.

Most of the morbid states of the spleen which possess clinical interest are considered in connection with diseases of the blood and with malaria.

SPLENITIS.—Splinitis occurs rarely as the result of extension of inflammation from a neighboring organ, such as the stomach, perinephric tissue, the diaphragm and lungs, or as the consequence of injury.

The symptoms are *tenderness* and *enlargement* in connection with the inflammatory conditions of adjacent organs referred to, and it is upon the association of such symptoms with those in the spleen itself that the diagnosis depends.

PERISPLENITIS.—This may occur as the result of the same causes as produce splenitis, and may be recognized by the presence of palpable friction fremitus.

ABSCESS OF THE SPLEEN.—Abscess of the spleen occurs along with pyemic processes elsewhere, in the presence of the usual causes of pyemia. Such abscess may break into the stomach, bowel, or lungs, as well as into the peritoneal cavity.

RUPTURE OF THE SPLEEN.—This arises from severe injury, also from extreme and sudden acute hyperemia, due to malignant malaria, and from

rapidly growing splenic tumors. The symptoms are sudden pain in the region of the spleen, collapse, pallor, and death, associated with the causes named.

THE AMYLOID SPLEEN.—This appears as a hard, smooth, and enlarged organ, associated with amyloid disease of other organs, such as the liver and kidneys, especially when there has been long-continued suppuration, as in hip disease, osteomyelitis, tubercular consumption, or syphilis.

ATROPHY OF THE SPLEEN.—On the other hand, the spleen may be reduced in size by fibroid overgrowth and contraction due to syphilis.

HEMORRHAGIC INFARCT OF THE SPLEEN.—Infectious hemorrhagic infarct results in abscess of the spleen. The non-infectious is the result of embolism by a non-infectious embolus, such as arises from the cardiac valves in acute or chronic endocarditis, from clots in the cavities of the left ventricle, or from clots in aneurysms in the large arteries. After the kidney, the spleen is the most frequent seat of such lodgment.

Symptoms.—The infarction is sometimes ushered in by chills, vomiting, and painful enlargement, the true nature of which can only be inferred when the causes named are present or the symptoms of embolism elsewhere occur simultaneously.

NEOPLASMS OF THE SPLEEN.—These are represented most frequently by gummy tumors, which are almost never recognized before death. *Carcinoma*, *sarcoma*, and *tuberculosis* occur, but are not recognizable by special characters. A nodular and uneven spleen may be regarded as due to cancer when associated with cancer elsewhere, sarcomatous when there is general sarcoma, tuberculous if there is tuberculosis elsewhere, and syphilitic if associated with the history of syphilis, especially the congenital form.

ECHINOCOCCUS OF THE SPLEEN.—The spleen may present a fluctuating tumor the nature of which can only be determined by the certain knowledge that a tumor of the same kind exists elsewhere, or by the recognition of hooklets in the aspirated fluid. Should the fluctuating tumor be associated with chills and fever, it is more likely to be abscess, which, it is to be remembered, may also begin as echinococcus disease which later takes on suppuration.

WANDERING SPLEEN.—This is a term applied to a condition of the spleen analogous to the movable kidney and liver. It is the direct result of an elongation of the gastrosplenic ligament and splenic artery and vein. Under these circumstances the usual splenic dullness in the midaxillary line, between the ninth and eleventh ribs, has disappeared, and the spleen can usually be felt elsewhere in the abdominal cavity, usually, however, on the side below its normal site, whence it may be pushed into the natural situation, to leave it immediately as the upright position is assumed. Rarely, it is found in more distant situations, even in the pelvis. At times it may form attachments by inflammatory adhesion in the new situations, making its restoration difficult or impossible.

Symptoms.—The symptoms are not unchanging. The most constant is a *dragging sensation*, while there may also be the *effects of pressure*, which

vary with the situation. There may be pressure on the ureter or bladder, causing difficulty in micturition; upon the bowel, causing partial obstruction or pain by the compression of sensitive parts. The same train of nervous symptoms which attends floating kidney may also be present.

Diagnosis.—Some difficulty of diagnosis may result in consequence of such vagueness of symptoms. There may be a question between the existence of wandering spleen and *fecal tumor*. With the former, the normal splenic dullness is wanting, though the well-known fact that the dullness is sometimes very small in health may give rise to error. A freely movable *cancer of the pylorus*, a tumor so movable that it may be felt in the left hypochondrium, may occasion similar difficulty, which must be settled in the same way. And so with other abdominal tumors of movable nature—the normal splenic dullness remains. The question as to whether a movable organ is the spleen or kidney is not likely to be a knotty one, even if the movable kidney be the left, if the same guide be availed of. The difference in outline of the two organs may be recognized in persons with thin abdominal walls, and, in rare instances, by the splenic notch. The possible coexistence of a movable spleen and a movable kidney is to be remembered.

Treatment.—The treatment must consist of mechanical measures to keep the spleen in place—measures which must be determined by the requirements of each case. They are variously successful.

DISEASES OF THE PERITONEUM.

ACUTE PERITONITIS.

Definition.—An acute inflammation of the peritoneal membrane.

Etiology.—Of *Primary Peritonitis*.—Primary peritonitis, or that form which originates independently of inflammation of adjacent structures, is spoken of as idiopathic in origin. It is a disease of such rarity that its existence may reasonably be questioned, and there are those who deny its occurrence *in toto*. Its reputed cause is exposure to cold.

2. Of *Secondary Peritonitis*.—By this is meant an inflammation the result of invasion of the peritoneum from a primary focus of disease somewhere in the vicinity, or traumatic agencies, like blows or punctures involving the peritoneum. Formerly, operations involving the peritoneum were fruitful causes of peritonitis, but since aseptic surgery has become general, such operations are done with an immunity previously undreamed of. There are two chief foci whence such inflammation originates. One of these is the digestive tract; the other, the genito-urinary system, more particularly of women. Inflammation may also invade the peritoneum from the liver, gall-bladder, spleen, or perinephritic region, or from Pott's disease or psoas abscess. Perforation of the stomach in ulcer or cancer, of the intestine in typhoid fever, appendicitis, and dysentery, are the commonest causes originating in the gastro-intestinal tract. The second focus is purulent inflammation of the Fallopian tubes and the genito-urinary tract. Endometritis and metritis may be the starting-point of such inflammation, which may extend up the Fallopian tube, or there may be parametritis with suppuration, the abscess arising from which may rupture into the peritoneal cavity. All of the different forms of secondary peritonitis are infectious, and caused either by organisms responsible for the primary disease or by

such as are set free with the gastric or intestinal contents by perforation. The organisms found under these circumstances are the *streptococcus pyogenes*, the *staphylococcus pyogenes aureus* or *albus*, and the *bacterium coli commune*, the latter especially after perforation of the appendix, also the *tubercle bacillus*. The *ameba coli* has been found in the peritoneal fluid in amebic dysentery. Peritonitis may also occur from infection from more distant foci of suppuration, when it is also called pyemic peritonitis.

Finally, peritonitis not infrequently becomes a complication of pleurisy, articular rheumatism, and nephritis by a process not thoroughly determined. The first is probably the result of extension by continuity, since the two cavities communicate by the lymph vessels of the diaphragm. The poison of rheumatism, whatever it is, may be the cause of the peritonitis, while the retained excreta which accumulate in the blood in Bright's disease may act similarly.

Morbid Anatomy.—This varies somewhat with the extent of the peritonitis and the duration of the attack. First, there may be a "general" or "diffuse" peritonitis, or it may be "circumscribed." In general peritonitis the peritoneal surface of the intestinal coils is hyperemic and covered more or less continuously with flakes of yellow lymph made up of fibrin and leukocytes. This is especially abundant in the sulci between the coils, while it also covers the convexity. In an earlier stage, before the exudate appears, the surface of the peritoneum is dull and rough, owing to a desquamation of the epithelium. In the flanks is found a variable amount of fluid, which may be serous, serofibrinous, or purulent, which, increasing, produces an appreciable ascites. In prolonged cases organization and vascularization from the capillaries of the peritoneum take place, the solid contingent being formed from the epithelium or wandering cells, resulting in adhesions between the coils of intestine and adjacent organs. These are at first soft and easily ruptured, but later become firm bands. These latter are, however, more common in the circumscribed form.

In circumscribed peritonitis limited areas of lymph formation occur and adhesions are more pronounced. Copious fibrinoserous exudate is less frequent, though sometimes quite large circumscribed collections of pus occur, laced off from the remainder of the peritoneal cavity by organized tissue. Such abscesses sometimes rupture into the general peritoneal cavity, producing general inflammation, collapse, and death.

Symptoms.—I. *Of an Acute General Peritonitis.*—The most decided symptom is *pain*, usually of extreme severity, which is commensurate in extent with that of the inflammation. There is also extreme *tenderness*, which is similarly limited. So great is this that any tension on the abdominal walls excites pain; hence the legs are drawn up to relieve this, and we have the well-known position almost characteristic of general peritonitis—dorsal decubitus, with the thighs flexed on the abdomen. Any motion such as straining, even the act of breathing and the emptying of the bladder, increases pain. From the nature of the causes this pain is usually sudden in occurrence, succeeding, as it does, on perforation, abscess rupture, and the like. Sometimes, indeed, it is the first intimation of any illness whatever. *Abdominal distention* is a third characteristic symptom of peritonitis, ascribed to a paralysis of the muscular coat of the bowel, and continues throughout the attack. Rarely, however, the abdomen is flat, hard, and board-like. As rarely, too, pain is altogether absent.

Among the symptoms which may usher in the attack is *vomiting*. It

is regarded as reflex in origin, excited by the inflammation of the peritoneum. The effort is sometimes ineffectual, and sometimes a perforation of the stomach permits the more ready discharge of its contents into the abdominal cavity. The vomitus consists of what happens to be in the stomach at the time, or of mucus and, if the symptom is prolonged, of green, bilious matter. The primary vomiting is followed by abatement and exacerbation.

The symptoms which are associated with these or succeed upon them vary with the nature of the cause and extent of the disease. In fulminating cases due to perforation of the bowel, as in typhoid and appendicitis, they are the symptoms of *collapse*—viz., *extreme weakness, cold, clammy skin, frequent, small, and feeble pulse*. The pulse exceeds 120 and often reaches 160 and even more. The breathing-rate is from 30 to 40. The temperature is slightly raised, remains about normal, or may be subnormal. Rarely, it is high,—104° to 105° F. (40° to 40.6° C.),—though the skin may feel cool and clammy. The expression is characteristic—Hippocratic. The eyes are sunken, the cheeks and temples are collapsed, and the nose is pinched. The urine is scanty and contains indican.

If the patient survive, the *physical signs* of effusion make their appearance. There is dullness on percussion, first in the flanks, whence it ascends as the fluid increases. If sufficiently abundant, the dullness becomes general and fluctuation may be recognized. Palpation and percussion both occasion pain. A change of position from the back to the side causes a change in the position of the fluid, and corresponding alterations in the physical signs. In severe cases the diaphragm is raised, the apex of the heart dislocated, and the liver dullness may be obliterated in the mammillary line by combined effusion and extreme tympany. Similar obliteration may happen to the splenic dullness. Both may be restored by turning the patient on his side. Such obliteration is, however, far more characteristic in what is known as *pneumoperitonitis*, a form of peritonitis caused by perforation from an air-containing organ into the peritoneal cavity, and of intense severity, excited by the pathogenic bacteria thus admitted. Acute pain, rapidly developing collapse, scarcely appreciable pulse, icy coldness of the skin, and great distention of the abdomen are the symptoms. The air, of course, occupies the highest part of the abdominal cavity, covering the liver and spleen, causing the obliteration referred to. The distinctive point in the diagnosis between pneumoperitonitis and the extreme degrees of the ordinary form is the fact that in the former hepatic dullness is absent even in the midaxillary line when the patient is on his left side, whereas, in simple peritonitis, hepatic dullness may be elicited when the patient is in this position, though it may not be if he is on his back.

Throughout all, the intellect is clear, and while there is often a total lack of realization of the inevitable and usually dreaded end, it is as often thoroughly appreciated by the patient and is viewed with a calmness which increases the awe which always attaches to the presence of the shadow of death. Rarely, in the course of his experience, is the physician called upon to witness a more painful scene. Toward the very end, however, a somnolence commonly supervenes which obscures the expiring moment, or a slight delirium, the visions of which may be interpreted by surrounding friends as the first glimpses into another world.

The course of such a case is steadily downward, reaching its end in from two to six days.

2. *Of Acute Circumscribed Peritonitis*.—The symptoms include those of

the general form in a very much milder degree. The pain is less severe and more circumscribed, the tenderness proportionate, while the definiteness of neither is very sharp. Vomiting may also usher in the attack, and may be similarly modified. There may likewise be the signs of collapse, and the patient is often very weak. There is, however, more decided and constant fever though remittent, as in septic fever generally, and the cases run a longer course, ending not rarely in recovery, but more frequently in death from exhaustion.

As already mentioned, circumscribed abscesses are more frequently recognized by fluctuation, and may even point toward the surface, while they are as liable to rupture into the general peritoneal cavity, producing there the symptoms and more usual fatal termination of general peritonitis. This mischievous termination, at the present day, is often prevented by the timely interference of the surgeon. As varieties of such abscess may be mentioned the perinephric abscess, the pelvic abscess, the subdiaphragmatic abscess, arising from perforation of the stomach or colon or disease of the liver or spleen, and the periappendicial abscess. The results of circumscribed peritonitis in children are sometimes seen in the shape of a painful, fluctuating tumor in the groin. Circumscribed peritonitis is also more or less associated with the symptoms of the disease which causes it.

Diagnosis.—That of general peritonitis is seldom difficult, especially in the fulminating variety. Some days may, however, elapse before the question is settled, for sometimes the symptoms are closely simulated by those of other conditions. Particularly is this the case with the extreme tympany and tenderness which are sometimes associated with *typhoid fever*, especially when there is deep-seated ulceration. It not rarely happens that on these symptoms is based the diagnosis of a peritonitis, which is not found at necropsy. *Enterocolitis* may give rise to similar symptoms. On the other hand, it has happened that grave and fatal peritonitis has eluded detection, having been found for the first time at autopsy.

Hysterical peritonitis is a term applied to a condition met with in women, when every symptom of acute peritonitis is simulated, even collapse itself. It is needless to say that patients do not die of this disease, and that time settles the question ultimately, and when there is recurrence, as is often the case, a second attack is not likely to mislead.

Acute hemorrhagic peritonitis should be mentioned as a variety, the symptoms of which sometimes are the same as those of the ordinary form.

Circumscribed peritonitis is more frequently difficult of detection, and its diagnosis often requires a knowledge of the presence of the causative disease to suggest it. Fluctuation is only available in diagnosis when there is superficial abscess. The exploring needle may, however, at times be availed of.

Prognosis.—This, in general peritonitis, is almost invariably fatal, only the mildest cases offering the possibility of recovery. Modern surgery has many times saved life even in peritonitis which succeeds perforation in typhoid fever, gastric ulcer, and perforated gall-bladder. The duration of most cases is from two to six days.

Localized peritonitis is a more promising malady. A few cases get well by spontaneous discharge of resulting abscesses, more with the assistance of the surgeon, and some neglected cases doubtless perish when timely aid from this source would have saved life.

Treatment.—The treatment of general peritonitis succeeding perfora-

ation consists for the most part of measures calculated to relieve the patient's sufferings while awaiting the end. If the opportune moment can be seized, a laparotomy may be performed, for life has been saved frequently; but no rule can be laid down which will aid in the selection of such a moment. Local measures looking toward cure, such as blisters and other counterirritating agencies, are useless. To relieve pain, the hot poultice or ice-bag may be used in turn. Sometimes one gives more relief, sometimes another. After this, opium may be administered in the minimum degree necessary to relieve pain. I see no advantage in the use of opium for any other purpose, unless it be also to allay vomiting. It has no effect in limiting the spread of the inflammation. When doubt as to diagnosis exists,—as to whether there is true peritonitis or painful distention of the bowel,—turpentine may be administered with full doses of strychnin, say 1-30 to 1-20 grain (0.002 to 0.003 gm.), while turpentine may be applied locally. Iced turpentine stupes are often exceptionally grateful. Turpentine enemata under these circumstances are of doubtful utility, in fact, may do more harm than good, and should be discouraged.

Special symptoms, such as nausea, faintness, and exhaustion, require the treatment usually appropriate to control them. For the first, ice by the mouth or locally, small doses of champagne, and counterirritation are useful. For failing strength, stimulants, local heat, hypodermic injections of ether, digitalis, brandy, and strychnin are available, but I do not approve of the practice, so often pursued by young hospital physicians, of indiscriminately plying these measures when they must evidently be unavailing.

The treatment of circumscribed peritonitis permits the use of local measures not admissible in the general form. Counterirritation by blisters, and especially blood-letting by leeches, is sometimes of signal service in relieving symptoms, and may even effect a cure if the primary causing disease is removed. The surgeon and the gynecologist should be early summoned, as it is more frequently through their assistance that a cure is accomplished.

CHRONIC PERITONITIS.

Etiology.—By far the largest majority of cases of chronic peritonitis are tubercular in origin. Some cases are caused by cancer and other morbid growths in the abdomen, while there are also others of simpler origin. Thus originating, we have both a circumscribed and a diffuse adhesive peritonitis. See also Section on Tuberculosis of the Peritoneum, p. 282.

LOCAL, CIRCUMSCRIBED, OR CHRONIC ADHESIVE PERITONITIS.

This occurs between adjacent organs, such as the spleen and diaphragm, liver and diaphragm, stomach and liver, and organs in similar relation, as the result of chronic disease in one or the other. These adhesive connections are not always close, but sometimes consist of bands of considerable length, such as have already been referred to as occasional causes of obstruction of the bowel.

Symptoms.—The symptoms of obstruction of the bowel are often the first evidence of the existence of such adhesive bands. Other symptoms are a sense of *restriction in the motion* of organs involved, with pain when such motion occurs; also *constipation, colicky pains*, and pains resulting from

traction exerted in peristalsis. Other vague symptoms occur which go to make the patient uncomfortable, but are not distinctive. Should a peritoneal friction, however, be felt, more conclusive evidence is thus furnished. Should suppuration attend chronic inflammation, more distinctive symptoms also arise. In addition to the pain and tenderness a *hectic fever* may be present, which may guide to a correct conclusion with or without the aid of the exploring needle or eventual rupture into one of the hollow abdominal organs.

DIFFUSE CHRONIC PERITONITIS.

This may succeed upon acute diffuse inflammation of mild degree, which is followed by an abatement in all the symptoms. It may occur in connection with chronic cardiac or hepatic disease where there has been long-continued venous stasis; or it may succeed the punctures of numerousappings and, most rarely, chronic intestinal disease.

Morbid Anatomy.—The peritoneum is thickened. The intestinal coils may be cemented to one another and to neighboring organs. The liver and spleen are sometimes covered by thick, tough, grisly capsules. The omentum and mesentery may be thickened and shrunken. There may be thickened nodules, not tubercular. There is in these cases rarely any considerable effusion. A hemorrhagic form, suggesting hemorrhagic pachymeningitis, was described by Virchow. It is more commonly situated in the pelvis and characterized by bloody effusion.

Symptoms.—These exhibit for the most part a diminished degree of those characteristics of acute peritonitis, to which may be added *tumor-like swellings and thickenings* and swelling difficult to interpret. Other vague symptoms are engendered by them as the result of contraction and pressure, including *pain, edema, albuminuria, irregularity of bowel action*, and sometimes *feverishness*. There is little that is characteristic unless it be the occasional presence of recognizable effusion. The very slow forms attended with extensive effusion are not separable from ascites, the result of hepatic disease, although there are differences in the effusion. In peritonitis the effusion is more turbid, contains abundant albumin, and has a specific gravity rather higher than the fluid of an ascites: 1018 as compared with 1012.

A chronic peritonitis not unusual in children from two to ten years old is described by Strümpell and others. It is associated with decided ascites, debility, and other symptoms of ill health more or less marked, while recovery is the usual termination. Such a cause for the ascites should not be assigned without careful search for others, especially disease of the liver.

Treatment.—The treatment must be determined by circumstances. It is chiefly palliative, unless operative interference promises more.

CANCER OF THE PERITONEUM.

Primary cancer of the peritoneum is an event of extreme rarity. Its occurrence as a true epithelial cancer must, however, be admitted. Colloid cancer also occurs as a diffuse and extensive growth, relatively firm, and without fluctuation. More frequently peritoneal cancer is secondary to cancer of the stomach, bowel, pancreas, uterus, or other organ; most frequently, perhaps, as an extension by contiguity, though also by metastasis. It occurs in the shape of *small or larger nodules* scattered over the peritoneum. The

former constitutes what is known as *miliary* carcinoma. The larger nodules are found in the omentum, in Douglas' cul-de-sac, around the navel and elsewhere, while the retroperitoneal glands may be simultaneously involved.

Symptoms.—These are those of chronic peritonitis, including effusion, with the added cachexia, and a diagnosis must be based on these, the antecedent history, and the possible presence of cancer elsewhere. The investigation must include the uterus and the rectum. The physical resemblance of the miliary form to tuberculosis is very marked, and in primary carcinoma the distinction is difficult. Palpation may recognize friction in both. In both the effusion may be bloody, but is more apt to be so in cancer than in tuberculosis. The test injection of tuberculin should be availed of. The cancerous patient is past middle life, the tubercular younger, tubercular peritonitis being especially frequent in children.

The possible presence of *echinococci* in the peritoneum is to be remembered. The local symptoms may resemble those of cancer very closely. The presence of hydatid tumors elsewhere, as in the liver, of course suggests the true nature of the simulating disease.

ASCITES.

SYNONYM.—*Hydroperitoneum*.

Definition.—Any freely movable collection of fluid in the abdominal cavity sufficiently copious to be recognizable by the physical signs furnished.

Etiology.—Ascites is a symptom of any one of a number of diseases causing venous engorgement of the vessels draining the peritoneum, but a symptom of such importance as to demand separate consideration. Its causes are local and remote. The most frequent local cause is obstruction to the portal circulation, commonly by some disease of the liver, especially hepatic cirrhosis. Any growth or inflammatory new formation in the gastrohepatic omentum or hepatic fissure exerting pressure on the portal vein may have the same effect. Abdominal tumors outside of the liver large enough to exert the requisite pressure may also produce ascites. Such are enlarged spleen and tumor of the ovary and even of the uterus. Chronic inflammation of the peritoneum, whether tubercular, cancerous, or simple, especially when the cancer and tuberculosis involve the omentum, is also a cause. More rarely cirrhosis and emphysema of the lungs and chronic pleurosy cause it. A rare and peculiar cause is adhesive pericarditis. Ascites thus caused is apt to be erroneously ascribed to cirrhosis of the liver.

Remote causes include, first of all, valvular heart disease, the general obstruction due to which causes ascites as a part of a general anasarca, the peritoneal cavity being the last invaded. Rarely, it is the only dropsical symptom of heart disease, in which event there must be associated some intermediate obstructing state of the liver. Bright's disease is also a cause of abdominal dropsy, in which disease, too, the peritoneum is, as a rule, last invaded. More rarely it occurs as a consequence of intense cachectic states, such as the gravest forms of anemia.

Symptoms.—Some fourteen to twenty pints (7 to 10 liters) are required before the physical signs to be described are developed. The abdominal cavity thus occupied is more or less distended, pendent when the patient is upright and widened when the patient is on his back, the flanks

dropping down and outward. The fluid also flows from one side to the other when the patient turns on his side. If the distention is excessive, "silver lines," such as extend across the abdomen in pregnancy, make their appearance, and the umbilicus is obliterated or protuberant. The superficial veins—branches of the epigastric—are distended and distinctly visible from pressure by the fluid on the vena cava, by which the return of blood from the lower extremities is interfered with. Sometimes these superficial veins from below are seen to join those of the mammary from above. Such distention, however, is often contributed to by coincident portal obstruction (see p. 461). There may also be edema of the lower extremities. There is no *caput medusæ* about the navel unless the portal circulation is also obstructed.

As intimated in the definition, the physical examination affords the most reliable evidence. To palpation there is the succussion wave, which is elicited by placing the palm of one hand on the side of the abdomen and tapping with the fingers on the opposite side. A false succussion wave is sometimes produced by this procedure in persons with fat, flabby belly walls, but error may be avoided by having an assistant place the edge of his hand vertically on the median line while the tapping is done, as in this way the false wave, which travels around through the abdominal wall, is obliterated. It is always difficult, and sometimes impossible, to palpate solid organs when the abdomen is distended with fluid. Such palpation is, however, facilitated by a modification of the ordinary method—viz., first applying lightly only the ends of the fingers, then suddenly depressing them, and so displacing the fluid that the solid organ can be felt.

Percussion elicits absolute dullness over the fluid, while over the bowels, which are floated upward, a tympanitic note is produced, which changes with the position of the patient. If there is considerable effusion and the patient lies on his back, there is a small oval area of tympany in the middle of the abdomen. If a small amount of fluid is present, the flanks only are filled in this position, and there is a large superficial area of tympany in front, which will be substituted by dullness if he be placed in the knee-elbow position.

The statement that in ascites there is dullness in the flanks must be taken with some allowance, for it sometimes happens that a tympanitic note may be produced by percussion far back in the flank behind the mid-axillary line, because in this situation lie the ascending and the descending colon, with the posterior aspect uncovered by peritoneum and therefore inaccessible to the fluid.

Differential Diagnosis.—The morbid condition which the physician is most frequently called upon to distinguish from ascites is probably the *ovarian cyst*. The ovarian cyst, especially when large, furnishes some points of resemblance, yet there are striking differences. It begins in one side and rises up from the pelvis toward the center of the abdomen, which soon becomes the most prominent portion, while the dropsical effusion spreads out into both flanks. The ovarian cyst distends one side more than the other at first, and continues to do this even when large and fully developed. It produces no obliteration or projection of the navel, as does abdominal dropsy. Palpation also recognizes fluctuation in the ovarian cyst, but it is usually less distinct and more circumscribed, while in ascites the wave passes all the way across the abdomen. To percussion, the latter condition affords a central tympany and dullness in the flanks, while in

ovarian cyst the flanks are resonant because the bowels are pushed into them. This is at least true of one flank, even if the other is completely occupied by a large tumor. If there is tympany in the upper abdomen, with an ovarian tumor, it is bounded below by a convex line, while in ascites its lower border is concave.

A change of position has less influence on the dullness in ovarian tumor than in ascites. Vaginal examination affords some information. In ascites the vaginal vault is obliterated, the uterus prolapsed, but freely movable, while in ovarian tumor the vagina is less encroached upon, the uterus being sometimes drawn up and less movable.

The characters of the contained fluid are, as a rule, widely different. The fluid of a simple ascites is usually transparent, has a low specific gravity, commonly below 1012, and contains a small quantity only of albumin and a few leukocytes. The ovarian fluid is usually dark and grumous in appearance, highly albuminous, with a specific gravity of 1020 or more, and reveals to microscopic examination numerous *granular fatty cells* (compound gran-

Fig. 39.—So-called "Ovarian Cells."

ule cells), cholesterin plates, and small, *pale granular cells*. These last are round or slightly oval, about the size of a white blood-corpuscle, and are by some regarded as pathognomonic of ovarian cyst contents, and therefore called "ovarian cells." They are found in pleuritic fluids, pus, and even ascitic fluids, but they are much less numerous in these. The cell is probably a degenerated endothelial cell from the peritoneum. The presence of these cells in large numbers is certainly a help to the identification of ovarian fluids.

In rare instances the fluid of ascites is milk-white. This occurs when from any cause there is leaking of chyle into the peritoneal cavity—*ascites chylosus*. In the effusion associated with morbid growths, such as cancer and tuberculosis, the fluid is also sometimes white in color, from the presence of an unusual number of fattily degenerated cells from these sources or from the peritoneal endothelium.

The *overdistended bladder* has been more than once punctured by mistake for ascitic fluid, but this accident can never occur if the patient is directed to empty his bladder or the catheter is used before tapping.

Hydronephrosis has been confounded with ascites, and this is less excusable than the confounding of hydronephrosis and ovarian cyst. In advanced hydronephrosis the fluid may be almost identical with that of ascites,

but its mode of development is from one side and exceedingly slow, while there are pain and tenderness in the region of the kidney. W. von Leube relates a case in which he mistook an enormously dilated stomach filled with fluid for ascites, and points out how easily the mistake could have been avoided by the previous use of a stomach-tube.

A *cyst of the omentum* is a rare condition, but should be remembered as a possible one to be distinguished from ascites.

Chronic peritonitis is also attended by effusion, which is, however, more limited than in ascites, and the change in the area of dullness on change of position is less complete because of the peritoneal adhesions, which interfere with the ready movement of the fluid. In tubercular peritonitis, where there is less limitation by adhesions, there is also tenderness. The withdrawn fluid is more highly albuminous and of higher specific gravity than the ascitic fluid.

Treatment.—The treatment of ascites is that of the causing disease. Paracentesis is often necessary to relieve the discomfort of the patient. The fluid may accumulate with rapidity and the tapping require to be repeated quite frequently, but it is not true, as commonly supposed by the laity, that a first tapping necessitates a second *per se*. When frequent tapping is necessary, it is sometimes better to keep the orifice open and allow the fluid to drain away continuously, rigid antiseptic precautions being taken. Under these circumstances the patient sometimes improves rapidly, as he is relieved from the exhausting effect of the pressure and weight of the large amount of liquid and of the constant dread of repeated tapplings.

SECTION III.

DISEASES OF THE RESPIRATORY SYSTEM.

DISEASES OF THE NOSE.

The first in the natural order of this system are the nasal passages. These are subject to but few medical diseases. They are explored from the front by nasal specula or dilators. The nares are investigated posteriorly by the rhinoscope, which is another name for a very small laryngeal mirror. The mirror is, however, introduced differently. The position of the patient in relation to the observer and source of illumination is much the same, but the head of the former is not raised, and the tongue is best held down by the tongue depressor or the forefinger. The warmed mirror is introduced with the reflecting surface upward, and is passed backward over the tongue behind the uvula until it lies against the posterior wall of the pharynx. It is then directed upward and forward, and upon it will be found the nasal image and that of the vault of the pharynx (see Fig. 40).

ACUTE RHINITIS.

SYNONYM.—*Coryza.*

Definition and Symptoms.—Simple acute inflammation of the nasal passages, giving rise to the well-known uncomfortable full feeling which all have experienced under the name of “cold in the head,” is a frequent event. There may be previous sneezing. The fullness is due to swelling of the mucous membrane, the result of inflammation, and is sooner or later followed by a discharge which, at first watery, may or may not become mucopurulent. With it comes relief of the most uncomfortable symptom, the nasal obstruction. This is most serious in nursing children, in whom it renders sucking often very difficult. There may be slight fever, but the constitutional disturbance is seldom decided, and the elevation of temperature is correspondingly trifling, rarely exceeding a degree. The nasal mucous membrane may be involved in diphtheria, constituting diphtheritic rhinitis.

Etiology.—Cold is the most frequent cause of simple acute rhinitis. The exudative forms, including simple fibrinous rhinitis and nasal diphtheria, are, of course, of an infectious nature.

Treatment.—When this condition is associated with inflammation of the adjacent mucous membrane of the respiratory passages and of the throat, its treatment is that of the concurrent affection. An ordinary cold in the head may sometimes be cut short by a full dose of quinin, if given early enough. When the discomfort is sufficient to require treatment, I have had excellent results from the inhalation of a solution of iodine in

ether, one or two grains to the ounce. The discomfort is partially due to the dryness, and this is overcome by the application of any simple ointment, as cold cream or vaselin, applied by means of a brush or the end of the finger. The same result is better accomplished by the oil spray, for which liquid paraffin may be used. Such applications to the adjacent parts are also useful when the discharge is irritating. In infants it is not unusual to apply the grease to the exterior of the nose, and it may be that some good effect is thus produced. Dobell's solution may also be sprayed into the nose, and when dry discharges accumulate, they should be washed out by gentle injections of tepid salt water. Dobell's solution is composed of

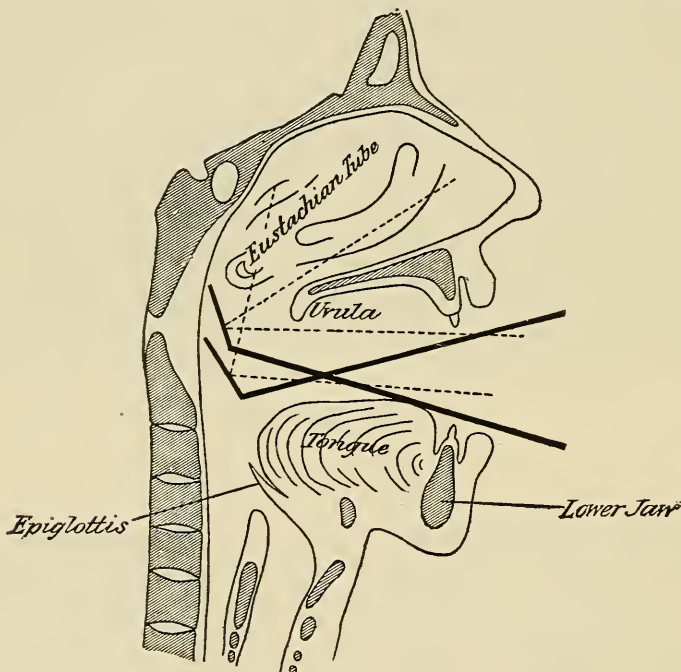

Fig. 40.—Illustrating Technique of Rhinoscopic Examination—(after Sahlz).

sodium borate one dram (4 gm.), sodium bicarbonate one dram (4 gm.), glycerite of carbolic acid (U. S. P.) two drams (8 gm.), and water one pint (0.5 liter).

CHRONIC NASAL CATARRH.

SYNONYMS.—*Chronic Rhinitis; Ozena.*

Definition.—Chronic inflammation of the nasal mucous membrane, associated with increased secretion and loss of the sense of smell.

Etiology.—Chronic catarrh of the nasal passages may be the result of acute inflammation frequently recurring, but more commonly it arises from special causes. Only a small number of the cases of rhinitis so common in the so-called scrofulous are the result of tuberculosis of the mucous membrane of the nose, but tuberculosis of the nasal passages does occur, and

must be recognized as a cause of chronic nasal catarrh. A more frequent cause is syphilis. It must be admitted, however, that these very persons known as "scrofulous"—that is, persons with fair, soft, and translucent skin, in whom inflammations run a slow course—are more subject to the disease, and that it arises in them either spontaneously or is excited by the more ordinary causes, such as recurring "colds." In consequence of the offensive odor frequently associated with one form of chronic nasal catarrh—the atrophic—it has been termed *ozena*.

Morbid Anatomy.—Two broad divisions of chronic nasal catarrh are made from the anatomical standpoint—the hypertrophic and the atrophic. In the *hypertrophic* there is a thickening of the mucous membrane, while in the *atrophic*, a thinning or atrophy is present. In the hypertrophic catarrh, the membrane is red, swollen, and spongy. The cavernous tissue over the turbinated bones shares in the process, and the nasal cavities may be encroached upon from all sides. The protrusion becomes more prominent as the disease progresses, and to it is added a greater or less hypersecretion of mucus.

In the *atrophic* or fetid form, the nasal mucous membrane is thinned, the cavities are enlarged, and within them are found the thick, yellowish-green crusts which, in decomposing, give rise to the characteristic offensive odor of this form of rhinitis. The atrophic process involves all the tissues, from the epithelium down to and including the underlying bone. The accessory sinuses connected with the nose—the frontal, ethmoidal, and maxillary—may all become implicated in this disease by extension from the nasal chambers, and may become the seats of chronic purulent inflammation.

Symptoms.—The two principal forms of nasal catarrh have certain symptoms in common. In both there is more or less *marked obstruction to nasal respiration*. In the hypertrophic form, however, this is due to actual narrowing of the nasal chambers by the overgrowth of the contained structures, while in the atrophic form it is due to the choking of the passages by the large masses of inspissated mucus and muco-pus. There is generally some slight *impairment of the sense of smell* in the hypertrophic form, while in the atrophic it is more often completely abolished. Both forms are usually accompanied by *disturbances of secretion* in the nasopharynx, and these lead to those noisy efforts at clearing the throat termed "hawking." The *ozena*, or fetid odor, is symptomatic only of the atrophic variety. No odor is attached to simple hypertrophic catarrh.

Hypertrophic nasal catarrh is apparently much more common in the United States of America than in Europe—indeed, the observations of the specialists go to show that almost every person is more or less the subject of these hypertrophic processes, of which, in many instances, he is quite ignorant until examination has shown their presence.

Treatment.—The proper local treatment of chronic nasal catarrh, which is by far the most important, demands such special measures as in the main can only be carried out by accomplished specialists. This treatment, therefore, so far as can be taken up in this book, can only be palliative, or, if curative, limited to the early stage of the disease. In all forms of chronic catarrh the most important measures to be employed by the physician, as distinguished from the specialist, are those which have for their purpose the attaining of the greatest amount of cleanliness of the affected regions. The simplest means for accomplishing this purpose is sniffing

from the palm of the hand simple salt solution of the strength of a teaspoonful of sodium chlorid to a pint (0.5 liter) of water, or some one of the substitutes named below.

This method, however, accomplishes the purpose but feebly, and the same solution can be more effectually introduced by the irrigator or nasal douche. There is much difference of opinion among specialists as to the efficiency and safety of the douche. Doubtless, harmful results have succeeded its careless use, among which are said to have been inflammation of the middle ear and meningitis. Carl Seiler claims, as did the late Dr. Elsberg, of New York, that these may be avoided by the observance of proper precautions. According to Seiler, the best irrigator is a tin vessel holding a pint (0.5 liter) and provided with an opening in its bottom, to which a rubber tube may be attached, furnished at the end by a nozzle made of glass, rubber, or wood which fits into the nostril. The vessel is filled with fluid, warmed to a temperature slightly above blood-heat, and the douche should be so placed upon a table or mantel that it does not stand more than an inch above the eyebrows of the patient. If higher, too great pressure may result, and the fluid be forced into the frontal sinuses, causing the frontal headache, or into the Eustachian tube, causing otitis media. The nozzle is introduced into one nostril, and the head being inclined forward, the water runs up in that side of the nose until it reaches the velum palati, when it passes around into the other side and through it, bathing the mucous membrane and washing out the mucus or loosening it so that it may be forced out by gentle blowing. It is important that the liquid used should be of the same temperature as the blood, and of the strength which is secured by the proportion named. The plain salt solution may be substituted by alkaline solutions, such as solutions of sodium bicarbonate and borate, of the strength of one dram (4 gm.) of either to the pint (0.5 liter), or of a half dram (2 gm.) of each combined. The douche sometimes fails of its purpose when the nasal passages are obstructed by deviation of the septum or bony hypertrophies. It should first be used carefully, therefore, under the direction of the physician, who will desist when he finds obstruction. It remains then to use the hand, as directed, or the nasal spray apparatus.

Whatever the dangers of the douche, they do not extend to the spray. As ordinarily used, it is, however, much less efficient. We may use with it varying proportions of "listerine"* and water, say from one to four up to equal parts; also an alkaline solution composed of listerine one part, water four parts, and a half dram (2 gm.) each of sodium bicarbonate and sodium borate. When large quantities are required to wash out the nasal cavities, the postnasal syringe may be used instead of the nasal douche. Listerine is disinfectant and deodorizing, but salicylic acid and carbolic acid may be added to solutions for these purposes. A plug of borated or salicylated cotton may be used for a like purpose.

Recently, Dr. J. Müller, of Vienna and Carlsbad, has availed himself of the pressure of condensed carbonic acid for producing the spray. He finds that a pressure equivalent to one and a half atmospheres is quite sufficient where a pressure of seven atmospheres by atmospheric air is necessary. Dr. Müller, when at Carlsbad, uses the water of the Sprudel Spring at blood-heat, and when at Vienna, an artificial Sprudel water. These sprays are played into each nostril ten to fifteen minutes at a time, and for

* For a formula for a solution similar to listerine, spts. thymol comp., see p. 320.

a like period into the fauces. This treatment is most searching, and yet harmless, as I can attest from a thorough personal examination.

General treatment, although not so important as the local, is still of great value, and the general health of the patient should be carefully looked after. In view of the fact that atrophic rhinitis is very apt to occur in scrofulous persons, cod-liver oil is a tonic always indicated, and should be given for a long time, intermitting occasionally to avoid derangement of the stomach. It should be associated with iron, and even with arsenic. Other tonics should be given as indicated, and the best of food should be prescribed, including an abundance of meat, eggs, and cream. Wholesome ventilation should be secured for the indoor life, while as much time should be spent in the open air as possible. The air indoors is especially apt to be contaminated by the breathing of the patient with atrophic rhinitis, and on this account good ventilation is imperative. If syphilis is present, it should receive appropriate treatment at once.

HAY FEVER.

SYNONYMS.—*Catarrhus æstivus; Hay Asthma; Autumnal Catarrh; Rose Cold; Pollen Catarrh; Vasomotor Coryza.*

Definition.—A catarrhal affection of the upper air-passages, associated with asthmatic dyspnea and occurring in the late summer or autumn and spring of the year.

Historical.—Hay fever was first described by Bostock, an English physician, in 1819, the description being based upon his own experience. He ascribed it to heat. Elliotson, in 1839, appears to have been the first to suggest pollen as its exciting cause. Blakely's observations in his own case (1873) confirmed this view, which is now generally held. Phoebus' classic work was published in Germany in 1862. The first elaborate work by an American was that of Wyman, of Cambridge. George M. Beard, of New York, in 1876 called attention to the neurotic factor. In 1877 Elias Marsh, of New Jersey, read a paper in which he added further evidence to the pollen theory. Voltolini, of Breslau, was the first to point out an anatomical cause—a nasal polyp, the removal of which was followed by the cure of the case. Since then numerous observers have added evidence in this direction, including Hack, in Germany, and Harrison Allen, Charles E. Sajous, William H. Daly, John O. Roe, and John N. Mackenzie in this country.

Etiology.—In a large proportion of cases, hay fever has as its fundamental condition an anatomical change in the nasal passages, such as hypertrophy of the mucous membrane, a polypoid growth, a deflection of the septum, or a lowered position of the inferior turbinated bones so that they rest upon the floor of the nose. These conditions are not always demonstrable, but they, or some allied source of reflex irritation, produce an irritability. This may be increased by a neurotic constitution, though the latter may not manifest itself until after the attacks have become habitual, so that at times, at least, it is more likely that the neurosis is a result, rather than a cause, of the disease. A third necessary etiological factor is an irritant. This irritant, whatever it is, originates usually in the spring or the late summer. In the spring, it has been regarded as coexistent with the fragrance of roses; hence the term, "rose cold." In the autumn, the pollen of flowering plants is commonly regarded as the exciting cause, and in certain instances this seems to have been conclusively demonstrated, as by Blakely in his own case. Other substances are, however, capable of acting similarly, and it is not unlikely that they are numerous. Changes of temperature

may excite attacks; also emotional causes, imaginary odors, and the like. Heredity is an important factor in its causation, successive generations being attacked with astonishing regularity.

Localities variously favor it. Generally, cities furnish more cases than the country, and low countries more than elevated ones, yet certain seaside places are absolute cures for many cases. Such a place is Long Beach, N. J., where is located Beach Haven, a seaside resort, fifty miles from Philadelphia, which has long been a resort for the victims of hay fever. The disease is more common in the United States than in Europe, and in the United States than elsewhere in America. It is more common in men than in women, there being three cases of the former to every two of the latter.

Morbid Anatomy.—There is no morbid anatomy other than that referred to in the remarks on the etiology of the disease.

Symptoms.—The onset of hay fever may be quite sudden, coming on with remarkable regularity often on the same day of the month each year. At other times it is more gradual in its onset. It frequently begins with *sneezing*, and, indeed, may consist entirely of inveterate sneezing. At other times there are *asthmatic attacks* of great severity, closely resembling those of bronchial asthma, constituting the "asthmatic type" of the disease. Again, there may be *obstinate cough*, with or without expectoration; or there may be an alternation of the two symptoms, but generally there is more or less persistent *shortness of breath*. There is also often great *depression of spirits*, and victims have even been impelled to suicide. The *eyes* are suffused with redness, and there may be conjunctivitis.

Diagnosis.—The diagnosis furnishes no difficulty. The season of the year and the periodical recurrence of the cough and asthma combine to make the recognition easy.

Prognosis.—Patients seldom die of hay asthma, yet I have known cases which seemed to be almost dying when they reached the haven which afforded them relief.

Treatment.—The *cure* of an individual attack is seldom accomplished except by removal from the district in which the patient resides. The White Mountains and the Adirondack Mountains are favorite resorts in the eastern part of the United States, and Bethlehem, N. H., is the Mecca of American hay-fever victims, though other places in the same neighborhood are equally exempt. The Catskills and Alleghanies are less celebrated. Certain seaside resorts have also a deserved reputation: Beach Haven, N. J., has already been mentioned; Fire Island, on the Atlantic Coast outside of New York Bay; the Isles of Shoals, Nantucket, and Mount Desert, on the New England coast, are others. Sometimes a sea voyage will abort a threatened attack, and some persons are quite exempt while at sea.

A few cases have been totally cured by operations on the nasal cavities, such as correcting deviations, and the removal of hypertrophic processes by the knife or actual cautery.

Home treatment, at best, is uncertain and but partially successful, and, as is always the case with a malady so difficult to cure, the number of remedies is legion. Of late, irrigation of the nasal passages by the nasal douche or spray with simple salt solution or weak solutions of quinin, one grain (0.065 gm.) to the ounce (15 c. c.), has been used, with varying results. Helmholtz was the first to suggest quinin solution, and thought it efficient. The oil spray is probably the most efficient measure of this kind. Cod-liver oil is preferred by some. A strong solution of cocain—4 to 10

per cent.—applied with a brush affords temporary relief, but the effect soon wears away, and there is danger of forming the cocain habit. Subnitrate of bismuth and boric acid, 1-2 dram (2 gm.) to the ounce (15 gm.) of vaselin or simple ointment, will sometimes allay the itching. Solution of suprarenal extract will be considered later. Boric acid, ten grains (0.65 gm.) to the ounce (30 c. c.) of water, may be used for the conjunctivitis.

It is usual to give quinin internally also, in doses of 10 to 15 grains (0.65 to 1 gm.) a day. Iodid of potassium and belladonna, so efficient in bronchial asthma, are of little use in hay asthma, but I have known them to be of service. The iodid is better given in small doses, frequently repeated, as 3 grains (0.2 gm.) every two hours. Fowler's solution has some reputation. Morphiu is undoubtedly a useful palliative, but its employment is to be deferred until other measures fail. From 1-8 to 1-2 grain (0.008 to 0.03 gm.) may be required, and the smaller doses should be tried first. Chloral is also of undoubted use as a palliative, and is much safer than morphin, with which it may be combined. It renders smaller doses of the anodyne more efficient, and may be given in combination with 1-24 to 1-12 grain (0.0027 to 0.0055 gm.) of morphin at short intervals. Suprarenal extract has acquired considerable reputation in the treatment of hay fever. S. Solis Cohen and Beamon Douglass were among the first to report favorably on its effect. It acts by reducing turgescence of the turbinated tissue. It is used externally and internally. For local applications a fresh solution is made by shaking the dried extract with water, and after allowing it to stand for an hour or two the clear solution is removed from the top and the precipitate discarded. In the shape of a spray the solution may be used every two hours until the symptoms have subsided, repeating the treatment on the appearance of obstruction, coryza, and sneezing. Internally it may be given in the tablet form or in a capsule. Five to ten grains are administered, day and night, every two hours until an examination of the nasal membrane shows that the vasomotor paralysis is under control, or until giddiness or palpitation is noticed. After this improvement the same dose may be given every three hours, then every six hours, and finally, only twice daily, which is continued during the hay-fever season. If the dose is too rapidly diminished and the symptoms reappear, one tablet should again be given every two hours until the symptoms are controlled. Mild cases may be comparatively comfortable during the season when the extract is used in this way. If the pure dried extract is used one to three grains may be given in a capsule.

DISEASES OF THE LARYNX.

Examination of the Larynx.—For the proper investigation of the morbid states of the larynx the laryngoscopic mirror has become almost as indispensable as the stethoscope in the study of diseases of the chest. Only under the most favorable circumstances, when direct sunlight is available, may it be used with natural light. In such event, the head-mirror, intended to direct the light upon the throat and laryngoscope, should be plane. Artificial light is far more convenient, and for its management a concave mirror is required. The light may be directed upon the throat by means of a condensing lens, but the mirror is not only more convenient, but also less costly. The patient should sit in front of the examiner, whose

eyes should be on a level with the mouth of the former, at a distance of about one foot. The convenience of a head-rest and a stool which can be raised or lowered to suit the stature of the patient is at once apparent. The light should be placed on the right of the patient's head, and a little behind it, at about the level of the ear. The head-mirror is then adjusted upon the middle of the examiner's forehead, no attention being paid to the central perforation. The patient's head should be slightly raised and the light reflected into the open mouth, of which a general survey should first be made. The patient's tongue is held down by a tongue depressor, or drawn out with the aid of a napkin, and may be held by the

Fig. 41.—Illustrating Technique of Laryngoscopic Examination—(after Sahli).

patient himself. The larynx is thus drawn up at the same time. The mirror, slightly warmed and tested upon the back of the hand, is then carried carefully over the tongue, between it and the palate, without touching either, or gagging will inevitably result, especially at the first examination. The uvula is gently pushed up by the mirror, and the handle carried to one side, and raised or lowered until the larynx comes into view. Practice is, of course, necessary to secure success. The patient is requested to say "Ah," in order that the epiglottis may be made to rise and the vocal cords approach each other.

As stated, much practice is required on the part of both patient and

physician to enable the latter to avail himself of the mirror in the most satisfactory manner. Some persons can barely allow the mouth to be approached, while others are not at all sensitive. The mirror should be at once withdrawn on the occurrence of gagging, and gradually its presence will be sufficiently endured. Various devices have been suggested for the

improvement of the illumination in the use of the laryngoscope, and they include the electric light, but for these the reader is referred to books especially devoted to the subject.

The best shape for the laryngeal mirror is, on the whole, circular, but special conditions may demand the oval form. Figure 42 shows the image at rest and during phonation.

ACUTE CATARRHAL LARYNGITIS.

Etiology.—The most common cause of catarrhal laryngitis is cold, but predisposition plays a most important part. Such predisposition may be the result of previous attacks of laryngitis, or it may be brought about by constant use of the organ in speaking and singing; whence it is common with persons thus engaged. In these occupations the larynx is hyperemic from overuse, and this hyperemia is ever ready to be fanned into active inflammation. Exposure to cold is constantly at hand to furnish the exciting cause. Laryngitis is also brought about by the inhalation of irritating vapors or gases, while intemperate smoking and the use of strong alcoholic drinks are also causes of the hyperemia so readily converted into an inflammation. Catarrhal laryngitis is frequently associated with catarrh of the adjacent parts, as of the nose and pharynx, trachea, and bronchi.

Morbid Anatomy.—It is characteristic of the mucous membrane of the larynx, and, indeed, of the trachea and larger bronchi below it, that it loses, postmortem, the anatomical characters of the inflammatory process as they appear during life. It is only by the image in the laryngeal mirror, therefore, that we can obtain an idea of these appearances as they present themselves during active inflammation. The picture thus obtained by the laryngeal mirror is one of intense redness, with swelling. These changes involve the true and false vocal cords and the trachea below, as well as the epiglottis

above. The latter appears in strong contrast to the yellowish-pink of health. Even greater is the contrast between the appearance of the vocal cords and the pearly white of health. If secretion has set in, streaks of mucus may be seen in places. Excessive swelling of these parts is known as edema of the glottis, but it is not frequent in simple acute laryngitis and will be described separately.

Symptoms.—The most constant symptoms of acute laryngitis are *hoarseness* and *cough*, which vary with the degree of the swelling and hyperemia, and which also give rise to a sense as of something present in the larynx and a constant desire to clear the throat. In high degrees of inflammation there may be *aphonia*. To these there is sometimes added *pain in deglutition*; with higher degree of inflammation there is a feeling of *constriction* or *oppression*. The cough is more or less *husky* and often stridulous. It is further characterized by its *dryness* and sometimes the act is *painful*. Both these features disappear with the establishment of secretion. There is generally a *slight febrile movement*, seldom very high. All of these symptoms are aggravated as the disease becomes more severe, culminating in the intense distress and impending suffocation accompanying *edema* of the glottis.

Treatment.—The patient should be kept in a uniformly warm, moist air, while special *inhalations* of such air are extremely useful both in giving him comfort and in abating the inflammation. They require no complicated apparatus. A piece of rubber tubing may be attached to the spout of a teapot or kettle, or the steam may be collected by an ordinary funnel and carried thence to the mouth. For obvious reasons, care should be taken that the funnel be not allowed to become too hot. Special appliances in the shape of a steam atomizer, more costly and scarcely more useful, may be used instead of the simple measures. *Cold applications* may be made to the outside of the throat. More rarely counterirritation by mustard may answer better. The irritative cough may require to be relieved by *anodynes*, which may consist of small doses of opium or some one of its preparations or derivatives. *Expectorants* are of doubtful value, and certainly are not nearly so useful as the simple measures which have been mentioned.

SPASMODIC CATARRHAL, OR FALSE CROUP.

Definition and Symptoms.—What is known as spasmodic croup in children of from one to five years is acute catarrhal laryngitis, to which is added a *spasm of the glottis*, producing the hard, stridulous breathing, with *croupy cough* characteristic of this affection, which, once heard, is never forgotten. It is produced by the same causes. To the croupy cough are added *extreme restlessness* and an *anxious expression*. The attacks generally come on suddenly at night, the child waking from a sound sleep, although warning is often given by some disturbance of respiration while the child still sleeps. There is little fever. The next day the child may appear almost or quite well, or there may be a slight croupy cough, yet there may occur another attack on the following night and even the third, while in very severe cases the recurrences continue for a week.

Diagnosis.—The only condition with which spasmodic croup can be confounded is diphtheritic croup, and then only if no membrane is visible.

The throat should always be examined. In diphtheria, suddenness of onset seldom occurs, and the child is much sicker previous to the croup. There is high fever and the anxiety of expression is much greater.

Prognosis.—The prognosis in all forms of acute laryngitis is generally favorable, and death is very rare from spasmodic croup. Carelessness may, however, prolong an attack.

Treatment.—The favorite measure to break the paroxysm of croup in children is an emetic. The simplest of emetics is ipecacuanha, which may be given in the shape of the wine or syrup in the dose of 1-2 dram to a dram (2 to 4 c. c.) every few minutes until vomiting is produced. The mineral emetics are more prompt, but more depressing in their action. An excellent remedy for the purpose is powdered alum with molasses or honey, which may be given in teaspoonful doses, repeated every ten or fifteen minutes until vomiting is produced, but it is not often necessary to give a second dose. While waiting for the action of the emetic the little patient may be put into a hot bath,—temperature 98° to 112° F. (36.7° to 44.4° C.),—and some mustard may be added. The temperature is kept up by the addition of hot water, as required. The majority of attacks of spasmodic croup may be broken up in this way without further treatment. Between the paroxysms the child should receive small doses of syrup or wine of ipecac, say five to ten minims (0.33 to 0.66 c. c.), until nausea is produced, or small doses of powder of ipecac conveniently in the shape of triturates containing 1-20 grain (0.003 gm.) for an infant a year old. An opiate is particularly useful at bedtime, and by means of it a child may often be tided through a night without an attack.

Just as early as possible in the treatment an aperient should be given, than which none is better than castor oil, but calomel is also an admirable remedy for children, given in doses of from one to three grains (0.06 to 0.2 gm.). When there is fever, aconite and sweet spirits of niter in appropriate doses should be given. Special pains should be taken to maintain a uniform temperature and avoid drafts, especially when the child is perspiring freely, and it is on this account that bed is the safest place.

Counterirritation by weak mustard plasters is an adjunct to treatment which should never be omitted, while gentle permanent irritation is very useful. It may be secured by any of the rubber-spread plasters now sold, known as porous plasters or caprine plasters. In severe cases, ice to the exterior of the throat, or cloths wrung out of iced water should be used, especially when there is much fever.

Parents are naturally anxious to secure some treatment by which the recurrence of attacks is prevented. It is to be remembered that a gradually increasing immunity comes with added years. Certainly no medicine can accomplish anything. It is possible, however, to do something by care and judicious outdoor life, by which is secured a "hardening" or protection against the more usual causes of laryngitis. As an instance of neglect of ordinary care may be mentioned the practice so common, especially among the poorer classes, of allowing children with their heads uncovered to be at an open doorway or open window in the cooler seasons of the year. Often a mother will be seen standing with her infant thus exposed in her arms. Such exposure is very apt to be followed by an attack of croup the same night. Children are also often too warmly clad while in the house, so that their bodies are constantly moist with perspiration. In this

condition a current of air, even when not very cold, will often produce spasmodic laryngitis. Children who are housed are much more susceptible to croup than those who spend a portion of each day in the open air.

SIMPLE CHRONIC CATARRHAL LARYNGITIS.

Etiology.—The causes of non-specific chronic catarrhal laryngitis are chiefly those which have been already mentioned as producing the predisposition to acute laryngitis—that is, the constant use of the voice in speaking and singing, excessive smoking, and the use of strong alcoholic drinks. Laryngitis occasioned by smoking and whisky-drinking is often accompanied by chronic granular pharyngitis. So, too, frequently recurring attacks of acute catarrhal laryngitis independent of predisposing cause, and the long-continued inhalation of slightly irritating substances are to be included among the causes of chronic inflammation.

Morbid Anatomy.—The morbid anatomy of simple chronic catarrhal laryngitis is commonly not widely different from that of the acute form. There are the same redness and swelling, but the former is less vivid. The chronic hoarseness which is so constantly associated with it is due to a permanent thickening of the parts concerned in the production of the voice. Ulceration is not common, although there may be superficial erosions. The follicular glands are often distended, and, if the inflammation is long kept up, a hyperplasia of the squamous epithelium may result in a moderate villous outgrowth on the cords. Nodular swellings on the vocal cords are also recognized, but rare, condition, known as *choriditis tuberosa* or *pachydermia laryngis*. Relaxation of one or both cords is often present, and maintains the voice symptoms as long as it continues.

Symptoms.—The most prominent symptom of chronic laryngitis is *hoarseness*, which is found in every degree from a simple roughness of the voice to almost entire loss of it. There are also more or less *pain* and *discomfort*, but these are not ordinarily conspicuous symptoms, except when an attempt is made to use the voice. There is a decided disposition to *cough*, with a view to getting rid of some foreign substance which seems to be in the larynx. The cough also varies in degree. It may be a mere hack, or it may be scraping or ringing. It is also variously effectual in bringing up a secretion of mucus and muco-pus, scanty for the most part.

Prognosis.—The prognosis of chronic catarrhal laryngitis is not encouraging for total recovery, largely, perhaps, because it is so difficult to induce the patient to comply with the conditions essential to his cure. Could this entire co-operation be secured, sometimes withheld through no fault of his own, it is not unlikely that better results would follow treatment.

Treatment.—The treatment of chronic catarrhal laryngitis requires, first, the removal of its causes, whatever they may be. The public speaker cannot expect to be cured of his malady while he continues the use of his voice, nor can the singer, or he who works among irritating vapors, nor the *bon vivant* who will not give up his alcohol. Next to the removal of the cause comes the use of local measures, for internal medication with a view to local effect is not promising. Of course, the patient's general condition must be looked after and his strength maintained, but local treatment is

mainly to be relied upon. Applications to the larynx may be made in four different ways:

1. By inhalation.
2. By lozenge or troche.
3. By insufflation.
4. Direct application.

The general practitioner must, in the main, confine himself to the first three, and much may be accomplished by them, particularly by the judicious use of the atomizer. Cases are rare in which the direct application of medicated substance to the larynx is necessary, and requiring as they do the simultaneous skillful use of the laryngeal mirror, they are for the most part relegated to the specialist.

Inhalations are further divided into three:

- (a) Nebulæ, or atomized fluid—sprays.
- (b) Steam or vapor.
- (c) Volatile substances.

1. A great variety of apparatus is employed for spraying medicated solutions into the larynx, and undoubtedly the most efficient is the compressed-air machine with spraying tubes, but the cheaper forms of atomizers are also useful. Many excellent machines are to be had, but rubber tubes are to be preferred where chemically active solutions are to be used. A double hand-ball secures a more continuous stream of spray than a single one. The spray should be thrown into the wide-open mouth, and advantage taken of inspiration to draw it into the larynx, and a very little practice will teach the patient how to accomplish this. Astringents are the favorite medicaments, of which alum and tannin are the most usual—of alum a 3 per cent. solution, 15 grains (1 gm.) to the ounce (30 c. c.) of water; of tannin, a 1 to 2 per cent. solution, 5 to 10 grains (0.32 to 0.65 gm.) to the ounce (30 c. c.). Other substances are sulphate of zinc, 15 grains (1 gm.) to the ounce (30 c. c.); chlorate of potash, 15 grains (1 gm.) to the ounce (30 c. c.); sulphate of iron and ammonia, 1-2 to 1 dram (2 to 4 gm.) to the ounce (30 c. c.). Before any of these solutions are used, however, the larynx should be cleansed from mucus by an alkaline spray, say Dobell's solution, or dilute listerine alkalinized.

Steam inhalation may consist of hot steam alone, or the vapor may be charged with a volatile substance. The efficiency of the former in acute laryngitis has already been referred to, and it is in acute disease that it is chiefly used. Benzoin, benzoic acid, and, for chronic conditions, cubebs and benzonate of ammonia are among the substances added. A teaspoonful of the compound tincture of benzoin may be added to a pint of water at 140° F. (60° C.), and placed in any one of the numerous inhalers, of which, however, none is better than an ordinary teapot. Volatile substances like nitrite of amyl are commonly inhaled for spasmodic bronchial disorders, to the treatment of which further allusion will be made.

2. The *lozenge* or *troche* is a favorite medium for medicating the larynx, and is often useful. Few have failed to realize the effect of a stimulating lozenge in clearing the throat, or the soothing effect of one of the anodyne or demulcent kind. An infinite variety is made, and the properties sought are stimulating, astringent, or anodyne, or a combination of two or more of these. Among the first is the lozenge of benzoic acid, the strength of 1-2 grain (0.03 gm.) to each lozenge; the cubeb lozenge contains from one to two grains (0.065 to 0.13 gm.) each; the ammonium chlorid

lozenge contains three to five grains (0.2 to 0.32 gm.); the potassium chlorate lozenge contains five grains (0.32 gm.). The astringent lozenge is made up of tannic acid one grain (0.065 gm.), catechu two grains (0.13 gm.), kino two grains (0.13 gm.), gallic acid two grains (0.13 gm.). Sedative lozenges contain opium in very small quantities, say 1-20 to 1-10 grain (0.002 to 0.006 gm.) in each, or of morphin 1-30 to 1-15 grain (0.002 to 0.004 gm.), lactucarium extract one grain (0.065 gm.), althea one grain (0.065 gm.). The selection of a suitable adjuvant in the preparation of lozenges is best left to the apothecary. Three to five lozenges a day at various intervals are allowed to dissolve in the mouth.

3. The treatment of the larynx by *insufflation* is sometimes very useful. The difficulty in the preparation of the powder is such that it may be irritating from a failure to secure sufficient subdivision of its constituents. The powder is applied by means of an instrument known as the insufflator. Starch is the basis of most of this class of remedies. Among the astringent powders are tannic acid and powdered starch, equal parts; alum and powdered starch, equal parts. Sedative powders contain of acetate of morphin two, five, eight, and ten grains (0.13, 0.32, 0.52, 0.65 gm.) to 1-2 ounce (15 gm.) of iodoform. Pure iodoform is also used; three drams each (12 gm.) of iodoform and subnitrate of bismuth with 1-2 ounce (15 gm.) powdered starch; also borate of sodium three drams (12 gm.), powdered starch 1-2 ounce (15 gm.).

4. *The direct application* is usually made by means of a brush, sponge, or cotton wad. The favorite remedy is the solution of nitrate of silver of the strength of from ten to fifteen grains (0.65 to 1 gm.) to the ounce (30 c. c.), the weaker solutions being first used, as they are often quite effectual. The application should only be made after considerable experience, and always with the aid of the laryngeal mirror, which, indeed, should be used whenever possible in making applications of any kind. Local treatment with nitrate of silver should be used every three or four days, the larynx being previously cleansed with a weak alkaline spray. Ten per cent. solution of resorcin in glycerin is a good application.

The selection of these various forms of medication in chronic laryngitis must be based on the requirements of the case, but the order in which they generally prove most useful seems to be about as follows, subject, however, to frequent variation:

1. Inhalation of medicated spray.
2. Inhalation of stimulating vapor, especially when there is much secretion.
3. Topical applications by the cotton wad.
4. Insufflation of powders.

Topical applications with the brush are likely to be made much earlier by the specialist than by the general practitioner.

The frequent association of chronic laryngitis with nose and throat conditions renders associated treatment necessary in these cases. In such, the method of spraying devised by J. Müller and described on p. 500 is an efficient aid.

TUBERCULAR LARYNGITIS.

Etiology.—The occurrence of primary tubercular laryngitis, long denied, has come to be generally conceded as possible, though rare. With the accepted view of the etiology of tubercular phthisis, tubercular laryngitis of the primary kind ought to be of frequent occurrence, for if the tubercle bacillus reaches the respiratory passages from without, the first point of attack would naturally be the larynx. The fact that such is not the case can only be explained on the ground that the bacillus fails to find in the mucous membrane of the larynx conditions as favorable for its growth and multiplication as it finds in the deeper portions of the lung. Since tuberculosis of the larynx is commonly secondary to the same affection of the lungs, the bacillus probably invades the larynx from the expectoration, inoculation being favored by the greater or less friction between the vocal cords. Tubercular laryngitis occurs as a complication of 20 to 25 per cent. of all cases of pulmonary tuberculosis.

Morbid Anatomy.—To the essential morbid anatomy of tubercular laryngitis is always added that of simple catarrhal laryngitis. The latter has been described. The first stage of miliary tuberculosis without ulceration is sometimes recognized by the laryngoscope, appearing sometimes as pearly granulations in the mucous membrane, more frequently as a less distinctive, close, small-celled infiltrate. The tubercular ulcer is more easily discovered, yet it possesses no one anatomical character by which it can be infallibly recognized. Nor are all the ulcers in the larynx associated with tuberculosis of the lungs necessarily tubercular. The larynx is more vulnerable to the ordinary causes of simple laryngitis under these circumstances, while the constant coughing and gagging in consumption may of themselves cause laryngitis. The true tubercular ulcer results from the caseation and disintegration of the miliary tubercle. The ulcer thus produced by the fusion of adjacent miliary tubercles is at one stage more or less characteristic by its racemose or sinuous edge, resembling in this respect the conglomerate tubercular ulcer elsewhere. Its favorite seat is the posterior part of the larynx, viz., the posterior part of the vocal cords, the interarytenoid fold and the laryngeal surface of the arytenoid cartilages. The epiglottis is less commonly invaded, and the ventricular bands more seldom. In the case of the epiglottis there is swelling, succeeded by ulcerations.

Symptoms.—The early symptoms of tubercular laryngitis differ in no way from those of simple catarrhal laryngitis, and it is the intractability of the disease which often gives the first intimation of its tubercular nature. The stage of simple *hoarseness* with which it is always ushered in varies also in duration, but sooner or later it is succeeded by the *aphonia* and the *painful whispering voice* which are so characteristic of ulceration of the vocal cords or the other parts intimately concerned in the production of the voice. Sooner or later, too, *painful deglutition* sets in as a result of the extension of the ulcerative process to the more exposed portions of the larynx. The pain on deglutition is often agonizing, and is due to the fact that during the act the constrictor muscles of the pharynx squeeze the sensitive epiglottis and arytenoids. Inanition and emaciation characteristic of the latter stages of the disease now rapidly increase, and death is often a welcome relief to the sufferer.

Diagnosis.—Just suspicion attaches to an obstinate laryngitis associated with acknowledged tuberculosis of the lung. With obstruction of the larynx the auscultatory signs of tuberculosis are sometimes wanting, so that we must depend on the percussion sounds entirely. As has been intimated, the distinctive features of the ulceration are scarcely sufficiently well marked to enable us to recognize the tubercular ulcer by the laryngoscope, and to distinguish it either from the *ulceration of syphilis* or that of certain stages of *malignant disease*. To distinguish it from the former, tuberculosis elsewhere and the history of the case may help to a conclusion, while in case of further doubt, the tuberculin test or the therapeutic test by iodids and mercurials may be used. Syphilitic laryngitis, even when it is ulcerative, quickly yields to these remedies, as a rule, while the tubercular condition is quite unaffected by them. With the healing of the former comes also the tendency to contraction so characteristic of all cicatrization, and especially of that of syphilitic ulcers. It is also to be remembered that syphilitic ulceration and tubercular ulceration are sometimes associated. The involvement of the tongue in the infiltrating and ulcerating process is more characteristic of tuberculosis.

Prognosis.—The prognosis of tubercular laryngitis is unfavorable at best. It is true that of late years the reported cures of laryngeal tuberculosis have become much more numerous, but these still bear a very small proportion to the cases that progress from bad to worse, in spite of the most skilled treatment. It is to be expected that primary tubercular laryngitis is much more easily curable than the form secondary to consumption of the lungs. Severe pain and signs of stenosis of the larynx are unfavorable symptoms.

Treatment.—All measures which have been mentioned as useful in the treatment of chronic catarrhal laryngitis are also more or less so in tubercular disease, with, however, less complete and less permanent results. Marvelous effects have been reported as following the use of lactic acid, while iodoform and even alkaline inhalations are also said to have healed tubercular ulcers. We hear much less of lactic acid of late. Two noteworthy cases illustrative of its efficiency are reported by Dr. Percy Kidd in "The Clinical Journal" (London), July 31, 1895. It requires the skill of the specialist for its application. All local treatment must be, of course, associated with that of general tuberculosis of the lungs. The painful deglutition, which is at once so characteristic and so distressing, has been relieved by the use of cocain applied directly to the larynx by the brush or by the spraying apparatus. The latter is the more convenient, because it can be used by the patient himself. For this purpose a 2 per cent. solution is suitable. A stronger—10 or 20 per cent.—may be necessary, but this must be applied with a brush by a second person. They should be used some minutes before the taking of food, as deglutition is rendered less painful for the time being by their successful application. Solutions of morphin may be sprayed for the same purpose, or the morphin, either pure or mixed with powder or starch, may be insufflated upon the painful larynx. When the pain is persistent and frequent applications are necessary, I have found none more satisfactory than the official solution of morphin sprayed into the larynx.

SYPHILITIC LARYNGITIS.

Etiology and Morbid Anatomy.—It is not necessary to dwell on the etiology of syphilitic laryngitis, as there is but one cause—the virus of syphilis. Syphilitic laryngitis may be either secondary or tertiary, and may occur at any time in the course of the disease subsequent to the second or third month following infection. Like tubercular laryngitis, the morbid anatomy of the syphilitic form is associated with that of simple catarrhal laryngitis of the chronic kind. Excessive mucous and muco-purulent secretions cover the surface of the epiglottis and the vocal cords, while the ulcer of syphilitic laryngitis is usually more distinctive in its characters than is that of tubercular laryngitis. The milder forms of syphilitic laryngitis are not accompanied by ulceration and are in no way peculiar, from the anatomical standpoint. The most distinctive anatomical manifestation of syphilis in the larynx is the mucous patch, like that on mucous membranes elsewhere. It is found on the epiglottis, in the laryngeal wall, and on the epiglottidean folds; rarely, on the vocal cords. The patches are rarely replaced by ulceration. The breaking down of the syphilitic gumma gives rise to another form of syphilitic ulcer, often of greater depth. The ulcer may come to a standstill at any stage, and cicatrization take place with deformity and permanent change of voice. In addition, necrosis of the laryngeal cartilages is not infrequent; portions of these being at times expectorated. Among the results of cicatrization are stenosis, resulting sometimes in complete obstruction, necessitating even tracheotomy for their relief.

Symptoms.—These are essentially the same as in tubercular laryngitis, hoarseness, cough, aphonia, pain in deglutition.

Diagnosis.—The diagnosis of syphilitic laryngitis is justified in the absence of tuberculosis elsewhere, especially when the history of primary syphilis is present.

Prognosis.—The prognosis of this form of laryngitis is rather more favorable than that of tubercular disease, especially if the diagnosis be made early. The effect of contraction after healing is, however, often serious in producing stenosis, or, at least, a permanent impairment of the voice.

Treatment.—The treatment of syphilitic laryngitis is the treatment for the general affection plus the topical treatment. The latter includes the use of measures to free the larynx of mucus and muco-pus, these being followed by applications of strong solutions of nitrate of silver to the ulcers, or even the solid stick. An insufflation of iodoform, in combination with bismuth and a little morphin, is an excellent addition to the treatment.

EDEMA OF THE GLOTTIS.

Definition.—By edema of the glottis is meant edema of those parts which immediately surround that opening.

Symptoms.—Its consideration has been deferred to this place because it so commonly results from the other conditions which have just been described, or accompanies them. Thus, it may occur in connection with acute laryngitis, though rarely, and occasionally with the tubercular and syphilitic form. It not infrequently, also, is a complication of general diseases attended with dropsy, especially Bright's disease, more rarely typhoid

fever, smallpox, and even diseases of the heart. In any of the latter conditions it may come on quite suddenly. The more precise situation is the sub-mucous tissue of the aryteno-epiglottic folds or of the ventricular bands. The edema may also involve the epiglottis. It occurs most frequently in middle life, but it also happens in the young.

An additional symptom of this condition is a feeling of *intense oppression* or *suffocation*. The *breathing is stridulous*, and the efforts of the patient to obtain air may bring into play all the extraordinary muscles of respiration, the whole expression being in extreme cases one of great anguish.

Treatment.—For the mild degrees of edema of the glottis the prompt application of a blister to the larynx is often sufficient to relieve the symptoms. Another remedy of some value in the milder cases is a direct spray, frequently repeated, of a solution of alum, 20 grains (1.3 gm.) to the fluid ounce (30 c. c.). In the treatment of the severer cases, cold plays an important rôle. Ice should be constantly kept in the mouth, as well as applied externally by means of ice-bags. If obtainable, the Leiter coil may be used. When danger is imminent, and time is too limited to wait for the tardy action of blisters, a half dozen or more leeches may be applied over the region of the larynx. These failing to afford relief, scarification of the edematous tissues is to be promptly performed, and, as *dernier resorts*, either intubation or tracheotomy.

The hypodermic administration of pilocarpin has been remarkably successful in some cases, and particularly when the symptoms are of a sthenic nature this should never be omitted. One-quarter of a grain (0.0165 gm.) is the proper dose thus administered.

PARALYSIS OF THE LARYNGEAL MUSCLES.

To understand these clearly it is necessary to remember—

1. That there are eight intrinsic muscles of the larynx, five of which are muscles of the vocal cords and rima glottidis, and three connected with the epiglottis. The former are the crico-thyroid, the posterior, and lateral crico-arytenoid, the arytenoid and the thyro-arytenoid. The muscles of the epiglottis are the thyro-epiglottideus and the superior and inferior aryteno-epiglottideus.

2. That the epiglottis is depressed by the thyro-epiglottidean and the aryteno-epiglottidean muscles. The aryteno-epiglottideus superior constricts the superior aperture of the larynx when it is drawn upward during deglutition and the opening closed by the epiglottis. The aryteno-epiglottideus inferior, together with fibers of the thyro-arytenoidei, compress the sacculus laryngis. The epiglottis is raised by the genio-hyo-glossus, the genio-hyoid, and the mylo-hyoid muscles.

3. That the separation of the vocal cords or opening of the glottis is accomplished by the posterior crico-arytenoid muscles alone, while its closure is effected by the lateral crico-arytenoids, the arytenoid muscle, and the thyro-arytenoids. The crico-thyroids, acting in conjunction with the arytenoid, become tensors of the vocal cords, producing the different degrees of tension necessary to delicate modulations of the voice in speaking or singing, while, at the same time, narrowing the opening of the glottis.

The right and left inferior or recurrent laryngeal nerves supply all the intrinsic muscles of the larynx on their respective sides except the crico-

thyroid, which derives its motor innervation from the superior laryngeal nerve.

This is the generally accepted view of the motor nerve supply to the larynx, although it has been shown to be subject to occasional variations. It is to be remembered that the motor fibers of these nerves are originally derived from the spinal accessory nerve by branches to the vagus before the latter leaves the cranial cavity. Consequently, motor paralysis may be due to: (1) Degenerative changes in the spinal accessory nuclei in the floor of the fourth ventricle; or (2) pressure on or destruction of the spinal accessory fibers before they join the vagus; or (3) degeneration, injury, or pressure suffered by the vagus trunk or its superior and inferior or recurrent branches; or (4) the paralysis may be myopathic.

As effects of one or more of these causes we may find the following conditions:

1. *Paralysis of the thyro-epiglottidean and aryteno-epiglottidean muscles*, resulting in a rigidly upright position of the epiglottis, and the opening of the superior aperture of the larynx.

2. *Paralysis of the crico-thyroid*, enfeebling the voice and lessening the ability to produce the higher tones. Examination by the laryngoscope discloses imperfect approximation of the cords, a lack of visible vibration in them, and, at times, if the paralysis be unilateral, a higher position of the unaffected cord.

3. *Laryngoplegia or total paralysis of a vocal cord*. This is usually the result of pressure upon the recurrent nerve trunk. If the paralysis is unilateral, the symptoms are not at all striking. Respiration is not affected; the voice, perhaps, is slightly modified and easily fatigued, but it is far from being wholly suppressed. Inspection by the mirror shows the affected cord in

Fig. 43.—Cadaveric Position of the Left Vocal Cord, Midway between Abduction and Adduction in Paralysis of the Crico-arytenoid Muscle due to lesion of the left Recurrent Laryngeal Nerve at the moment of Inspiration—(after von Ziemssen).

Fig. 44.—Complete Both-sided Abductor Paralysis of the Posterior Crico-arytenoid Muscles (the Openers of the Larynx) at the Moment of Inspiration—(after von Ziemssen).

what is called the “cadaveric” position, one that is midway between abduction and adduction. On phonation, the sound cord is seen to pass beyond the median line and approximate itself more or less closely to the other. The corresponding arytenoid cartilage is also drawn in front of that of the affected side, and the glottis is thus given an oblique position (see Fig. 43).

In bilateral recurrent laryngeal paralysis both cords are in the cadaveric position, and remain so both during respiration and upon attempted phonation.

4. *Paralysis of the abductors of the glottis, the posterior crico-arytenoid muscles*. Unilateral abductor paralysis due to pressure upon the recurrent nerve is not uncommon. The affected cord remains in the middle line in

consequence of the unopposed action of the adductor muscle. Phonation is not interfered with, and dyspnea occurs only in case of severe exertion, so that this affection is, doubtless, often overlooked.

Bilateral abductor paralysis is rare, and is generally dependent upon central degenerative change. The cords are found in the middle line with but a very narrow chink between them, and respiration is consequently noisy and much embarrassed. Slight exertion or emotional disturbance may provoke alarming dyspnea, and at times prompt tracheotomy becomes necessary (see Fig. 44).

5. *Paralysis of the thyro-arytenoid muscles*, whose office is to relax and approximate the vocal cords. This is usually bilateral and is quite common. It may be caused by voice strain, by exposure to cold, or it may accompany catarrhal laryngitis. Approximation of the cords is incomplete, an elliptical

Position in laryngitis of the vocal cords during phonation, the respiratory glottis remaining open.

space remaining between them which leads to hoarseness and feebleness of the voice. The laryngoscopic appearance is seen in Figure 45.

6. *Paralysis of the arytenoid muscles*. This may occur alone, the usual causes being cold, catarrhal laryngitis, or hysteria. A triangular gap is found between the vocal processes in attempted phonation, and the voice is very feeble or wholly extinct (see Fig. 46).

Fig. 47.—Bilateral Paralysis of the Thyro-arytenoids Combined with Paresis of the Arytenoid.

7. *Combined paralysis of the arytenoid and thyro-arytenoid muscles*. In this condition the mirror discovers a narrow, hour-glass opening between the cords, caused by the suspended activity of these muscles, while the lateral crico-arytenoids bring the tips of the vocal processes together (Fig. 46).

Etiology.—The causes producing paralysis of these muscles are largely

pressure by morbid growths within and without the larynx, among the latter being conspicuously aneurysm of the arch of the aorta and mediastinal tumors. Laryngitis and hysteria are also frequent causes.

Treatment.—The first effort of treatment in all these conditions should be directed to the removal of their causes. Unless this be possible, the prognosis is necessarily unfavorable. Catarrhal processes must be cured. The asthenia following diphtheria is to be overcome by general tonics and nerve invigorants. Electricity is frequently of great value, the galvanic or faradic currents being selected as each case may require. Hysterical paralyses are best treated by electricity, chiefly for the moral effect. Brilliant results often succeed this treatment, but relapses frequently occur.

DISEASES OF THE TRACHEA AND BRONCHIAL TUBES.

ACUTE BRONCHITIS.

SYNONYMS.—*Acute Bronchial Catarrh; Acute Tracheobronchitis.*

Definition.—An acute inflammation of the tracheal and bronchial mucous membrane. It is essentially a symmetrical disease, the bronchial tree in both lungs being more or less uniformly invaded.

Etiology.—The most frequent cause of acute bronchitis is the action of cold in chilling the body. It often succeeds an ordinary coryza or cold in the head or a laryngitis, the inflammation extending from the upper air-passages downward. It is naturally more prevalent in the winter than in the summer. It is usually a symptom of influenza, whether epidemic or sporadic. Invariably, too, it accompanies measles, of which it is the most annoying symptom. More rarely it is caused by irritating fumes. A microbic origin of acute bronchitis is possible in certain cases, but such origin cannot supplant the more usual causes described.

Morbid Anatomy.—The mucous membrane of the trachea and large bronchi is congested and more or less covered with a tough mucus, rich in cells, the hyperemia being especially marked about the glands whence comes the secretion. Decided cellular infiltration of the mucosa does not occur in ordinary cases, because of the almost tendinous basement membrane which intervenes between the blood-vessels and the mucosa.

Symptoms.—*Cough* is the most constant and conspicuous symptom. At the beginning it is hard and dry, without expectoration; sometimes it is painful. As the disease advances it gradually becomes looser. In the milder degrees there is no shortness of breath, but in the severe there is a varying degree of *dyspnea* with a sense of *oppression* or *constriction in the front of the chest*, caused by stenosis of the bronchial lumina, due to the swelling of the mucous membrane and the presence of secretion. *Fever* in mild degree is commonly present, but the temperature rarely exceeds 101° F. (38.3° C.). If it does, there is reason to suspect a more deep-seated involvement of the smallest or capillary tubules, whence the name capillary bronchitis, referred to in considering bronchopneumonia. This extension is particularly apt to take place in children and old persons, in whom the physician should always be on the lookout for it. With the access of fever the *pulse* is correspondingly accelerated. *Rarely*, a *chill* may usher in the disease.

The scanty *expectoration* of acute bronchitis is at first glairy or mucoid,

and later muco-purulent. With the appearance of the latter the cellular element, composed of pus-cells and desquamated epithelium, becomes more abundant. With the abatement of the disease the pus-cells become again less numerous and finally disappear.

Physical Signs.—There may be absolutely no physical signs—inspection, palpation, percussion, and auscultation being alike negative. In other cases inspection may recognize increased frequency of breathing, and possibly increased rate of the cardiac apex-beat if there be fever. Palpation may appreciate a rhonchal fremitus if there be sufficient narrowing of the breathing tubes. It may be found anywhere on either side, and is usually transient. Percussion continues invariably clear so long as the bronchitis is uncomplicated. Auscultation furnishes the most distinctive and constant physical sign, the presence of dry râles, the sonorous and sibilant, which may invade either or both lungs, and may also be transient, coming and going. To these may be added harshness of breathing sounds. When resolution sets in, bubbling râles may take the place of the sonorous and sibilant, in consequence of the presence of liquid secretion. For physical signs of capillary bronchitis see Bronchopneumonia.

Diagnosis.—This is generally easy. The presence of the dry râles and a clear percussion note belong to no other condition than acute bronchitis and bronchial asthma, but to the latter are added the signs of spasmodic contraction of the bronchi, notably the panting breathing. The same clearness of percussion note continues with the appearance of moist râles, unless there be the complication of capillary bronchitis or pneumonia.

Prognosis.—Very often the symptoms subside without treatment in the course of two or three days. The cough becomes loose, expectoration is easy, fever and other unpleasant symptoms disappear, and in a week the patient is well. Suitable treatment may hasten such an issue. In other instances, especially in persons who are weak and debilitated, no such speedy termination takes place, but even in many of these after a long interval the patient recovers. More rarely, particularly in the very young and old, the inflammation travels down into the smallest tubes, producing the capillary bronchitis alluded to. In other instances still, especially after several attacks, and in the old particularly, chronic bronchitis may supervene with the symptoms and physical signs which will be described when considering it.

Treatment.—The best treatment for a case of ordinary acute bronchitis is “the bed.” Twenty-four to forty-eight hours in a warm bed will go farther to cure such a case promptly than all the cough medicines ever prescribed. Such a course is not, however, always possible, and the physician is often expected to cure acute bronchitis while the patient is on his feet and even attending to business. The patient should, however, be put to bed if possible. Next to rest in bed is counterirritation. Turpentine and mustard are the best agents. A turpentine stupe or weak mustard-plaster applied to the front of the chest will aid greatly in allaying cough and relieving the sense of oppression.

Cough medicines are, of course, expected, and are useful. In the ordinary simple bronchitis, especially when there is moderate fever, there are few remedies more efficient than the simple solution of citrate of potash of the United States Pharmacopeia, in doses of 1-2 ounce (15 c. c.) every two hours. It may be desirable to add a few drops of wine of ipecac or wine of antimony to each dose to increase the relaxing effect, while, if the fever is decided, one minim (0.055 c. c.) of the tincture of aconite will aid in breaking it. A

diaphoretic effect is further encouraged by adding thirty minims (2 c. c.) of the spirit of nitrous ether. By such measures the cough is usually loosened in twenty-four hours, the dry râles are substituted by moist ones, and convalescence progresses. If there is decided oppression, it may be relieved by inhaling the steam from a hot saturated solution of chlorid of ammonium, or the compound tincture of benzoin floated on hot water, while in children an emetic dose of ipecac may produce the desired relaxation.

The cough may, however, be so constant as to harass the patient and keep him awake in spite of the measures suggested. In this event an opiate is necessary, and a small quantity of morphin, say 1-16 to 1-12 grain (0.004 to 0.0055 gm.) for an adult, may be added to the combination previously recommended. It is, perhaps, on the whole better to administer the opium separately, and of all the preparations, Dover's powder is probably the best. Indeed, Dover's powder alone is one of the best medicines in acute cough in doses of 2 1-2 grains (0.16 gm.) every two hours, preferably in a pill or capsule; or if it be at night and a prompt effect be desired, five grains (0.32 gm.) or even ten grains (0.65 gm.) in one dose will often act like a charm. Codein is a good preparation of opium, and has the advantage of disturbing the system less than some others. It may be given in doses of 1-4 to 1-2 grain (0.016 to 0.032 gm.) as often as necessary to quiet cough. Heroin is a popular modern remedy of this class, given in doses of 1-20 to 1-12 of a grain (0.003 to 0.0055 gm.).

Should convalescence be slow and expectoration prolonged, the ammonium chlorid in five- to ten-grain (0.32 to 0.65 gm.) doses with syrup or tincture of squills may be substituted for the sedative mixture, and quinin and restorative measures added to the treatment. If the cough is paroxysmal, the preparations of belladonna may be given, and are often efficient in controlling the paroxysms where opium is contra-indicated or deemed unnecessary. So, too, when secretion is copious and cannot be expectorated, belladonna tends to diminish it, and may be given with expectation of relief. Copious secretion in children is somewhat removed by an emetic. To this end alum and honey may be given or syrup of ipecacuanha in teaspoonful doses. All such measures are, however, depressing and may be succeeded by recurrence of secretion, and should be used only when necessary.

CHRONIC BRONCHITIS.

SYNONYM.—*Chronic Bronchial Catarrh.*

Definition.—A chronic inflammation of the mucous lining of the large and medium-sized bronchial tubes, commonly symmetrical.

Etiology.—Uncomplicated and primary chronic bronchitis usually develops gradually, representing the accumulating remnants of frequently recurring "colds," each of which leaves something behind it until the chronic condition is established. A bronchitis that is associated with or consequent upon another disease may continue and become chronic after the disease has disappeared. This may happen with measles or influenza, or even, rarely, pneumonia.

Chronic bronchitis constantly attends other affections as a consequence. The most common of these causes is tubercular consumption, but it is also the result of diseases which favor congestion of the air-tubes by reason of

the obstruction to the circulation which they cause, such as cardiac valvular disease. Especially is this true of mitral disease and Bright's disease.

Morbid Anatomy.—The bronchial mucous membrane is bathed with a dirty gray secretion derived from the mucous glands, which are sometimes hypertrophied. The darker color is due to inhaled "blacks," exfoliated degenerate cells, and sometimes to decomposed blood. On scraping this mucus away, there may be little or no change of appearance; at other times there may be a decided hyperemia. In places the mucous membrane may be thickened by cellular infiltration; at others it may be thinned, producing sometimes a lattice-like appearance, because of the prominence of the bands of elastic tissue which resist the atrophic process. In old cases there is often dilatation, which may be saccular, fusiform, or cylindrical, and sometimes cavernous dilatations are present, usually about the center of the lung. It is in the latter more particularly that the mucous membrane is found thinned and the mucous glands atrophied; at others, ulcerated. In other old cases there are ulceration and necrosis of the cartilaginous rings.

Symptoms and Course.—The chief symptom of chronic bronchitis is *cough*, which is troublesome in various degrees, and is apt to be worse at night or in the morning. Frequently it is paroxysmal, the spells terminating in free expectoration of the secretion which has excited the coughing.

Chronic bronchitis is commonly attended with *free expectoration*, either in the manner just described or more uniformly distributed through the day. The expectorated matter is usually muco-purulent or purulent, the color deepening to yellow as the proportion of pus corpuscles increases, and becoming darker in hue with the admixture of dead epithelium and decomposed blood. The quantity is sometimes very large, amounting to 1-2 liter (a pint) or more in the twenty-four hours. As the quantity increases, however, the consistence diminishes, and it may be thin and watery. To such copious expectoration the name of *bronchorrhea* is applied. More commonly it is purulent, containing greenish-yellow masses which are coughed up easily. The bronchi are usually more or less dilated in these cases. The more copious secretion of bronchorrhea or bronchial blennorrhœa usually separates, on standing, into two portions—a superficial sero-mucous portion, which may be frothy, and a lower thick portion made up more largely of pus-cells. In addition to such pus-cells the microscope discovers squamous epithelium from the mouth, columnar cells from the deeper air-passages, bacteria, and sometimes a few blood-corpuscles, as well as the delicate whetstone-shaped crystals known as Charcot's crystals.

Respiration is accelerated in various degrees, but except in the rare forms to be described and on exertion, dyspnea is never so marked as even in mild cases of tubercular consumption. The absence of fever is characteristic as contrasted with tubercular consumption, which chronic bronchitis so often resembles in other respects. Sometimes there is slight elevation of temperature, rarely exceeding 100° F. (37.8° C.).

After chronic bronchitis has existed for a long time in the old, especially when secretion continues copious while expectoration becomes difficult, there sometimes supervenes a condition of *low fever*, probably septic, from absorption of putrid matters, and unless expectoration can be re-established, the patient sinks and the fatal end is not very remote.

The appetite commonly remains quite good, and the patient maintains his weight for a long time. After a while, however, the appetite and digestion are apt to fail, especially if there is much expectoration, and then the

patient loses weight. Some subjects of chronic bronchial catarrh remain quite corpulent and well nourished throughout a long illness, and except for the cough, the amount of disturbance is often remarkably slight. There is no pain, except sometimes about the attachment of the diaphragm in the lower thorax in consequence of the harassing cough.

A variety of chronic bronchitis is the *asthma humidum* of the older authors, called by Laennec *catarrhe pituiteux*. It is characterized by still more copious serous expectoration, amounting sometimes to two liters (quarts) in the twenty-four hours of thin, frothy sputum, and by severe paroxysms of coughing.

Rarely, the cough is "dry," without expectoration except small, tough, tenacious masses of mucoid matter. These are brought up after paroxysms of coughing, often of great severity. This dry variety—the *catarrhe sec* of Laennec—is commonly associated with emphysema, and is a very troublesome form.

Still another variety of chronic bronchitis is well called *putrid* or *fetid* bronchitis, in which the secretions decompose in the air-passages and acquire a sweetish, sickening, and disgusting odor, which may pervade an entire apartment and make the patient a nuisance to himself and others. The decomposition is due to the bacteria of decomposition, the action of which is doubtless favored by retention of secretion in dilated bronchi and phthisical cavities, and in a decided majority of cases it succeeds an ordinary chronic bronchitis. It also sometimes follows an empyema which perforates into the lung. At times it is said to be primary. The expectoration is copious and correspondingly thin. It also separates into layers: an upper one of frothy, muco-purulent matter in which occur separate masses, and an inferior of thicker, greasy, purulent matter. In the latter the naked eye often recognizes dirty gray masses about as large as a pea, known as Dittrich's plugs, which on microscopic examination are found to contain pus, bacteria, and detritus of uncertain origin, together with delicate acicular fat crystals. Among other fungi are found also leptothrix filaments, which must not be mistaken for elastic tissue.

The chief additional symptoms are *fever*—it may be septic—with increase of cough and pain in the side. There is also sometimes a *chill*. These symptoms may again abate and those of the more usual form of chronic bronchitis prevail, subject to exacerbation and improvement. The effect of the fetid form, as might be expected, is more severe on the constitution, and there are loss of appetite, indigestion, and failing health. The fingers may be clubbed, as in phthisis. Secondary purulent meningitis and abscess have appeared from the transfer of pus germs. The physical signs do not differ from those of chronic bronchitis and bronchiectasis, to be described.

Physical Signs.—Physical signs of a decided character more constantly attend chronic bronchitis than acute. They present, however, no unchanging picture. There may be nothing apparent to inspection, or the frequently associated complication of emphysema of the lungs may be the cause of a diminished excursion of respiratory motion, and the roundness or barrel shape of the chest characteristic of that disease may be seen. Such emphysema may give diminution of the normal tactile fremitus and to percussion a hyper-resonance. In the vicinity of a superficial dilated bronchus filled with secretion there may be impairment of resonance. The resonance is, however, restored after copious expectoration, or the percussion signs of a cavity may

be substituted, though in the middle or lower part of a lung instead of the apex, as in consumption. Vesiculo-tympanitic or even tympanitic resonance may be present from relaxation of lung tissue, especially in the lower posterior part of the lungs.

Auscultation may also be negative, but much more frequently recognizes an alteration or combination of harsh and feeble breathing, sonorous and sibilant râles, with moist râles of all sizes, variously modified by different distances from the ear and varying consistence of the secretion. The moist râle is the most characteristic sign of chronic bronchitis.

Diagnosis.—This is not usually difficult, for while the symptoms, including coarser appearance of the sputum, sometimes closely resemble those of tubercular consumption, the physical signs do not, except when a dilated bronchus presents the same signs as a cavity. Such a dilatation is, however, found in the middle of the lung, and furnishes its signs in the neighborhood of the angle of the scapula, rather than at the apex. The absence of fever and especially of tubercle bacilli from the sputum after careful examination is confirmatory evidence of the absence of tubercular consumption, but above all, the tuberculin test will settle the question.

Prognosis.—This is unfavorable as to recovery, but favorable as to termination. The patient rarely dies of the direct effect of the disease, being generally carried off by some intercurrent affection, often croupous pneumonia. In the old, however, a condition described on page 521 may intervene, or a bronchopneumonia may supervene and terminate fatally. On the other hand, many patients the subject of chronic bronchitis live for years in comparative comfort, getting almost well in the summer and relapsing in the winter.

Treatment.—If it were possible to remove every person with simple chronic bronchitis uncomplicated by heart or kidney disease to a warm *climate*, they would probably get well. Certainly is this true of the earlier stages. Much may, however, be done at home to prevent the exacerbations due to cold, each of which adds a little to the previous chronic condition, by care in avoiding exposure. This consists mainly in dressing warmly and remaining indoors in bad weather. Heretical as it may seem, my experience teaches me that old persons can better bear a little "bad air" than "cold air," and it is wiser to submit to a little "closeness" than to encounter very cold air for the sake of "ventilation"; it is, of course, better to have both, if possible. It is especially important that the old should be warmly clad with wool next the skin, and precautions against cold feet should be especially secured. When bronchitis complicates other diseases, as heart disease and kidney disease, the treatment of these is important.

In the way of medicine, much can be done by the *stimulating expectorants*. The terebinthines are the best, and of these one of the best is terebene. Five to ten minims (0.3 to 0.6 c. c.) in a capsule every three hours is a proper dose. Terpene, another derivative of turpentine, may be given in doses of 1 1-2 grains (0.1 gm.) in pill as often, or it may be given in mixture with enough alcohol to dissolve it. Turpentine itself is a good remedy, in doses of from ten to twenty minims (0.6 to 1.3 c. c.). Creasote is an admirable remedy in chronic bronchitis: one grain or minim (0.06 c. c.) or two minims (0.12 c. c.) three times a day, increased gradually to five grains (0.3 c. c.), or even more than three times a day, will after a while diminish the secretion and the cough. Creasotol, or the carbonate of creasote, is a much more pleasant remedy, and may be given in doses of ten minims

(0.6 c. c.), which may be increased. Sandalwood oil or balsam of tolu or Peru may be substituted. The compound tincture of benzoin is another old but good remedy. Other stimulating expectorants, like the carbonate of ammonium or the aromatic spirit of ammonium, are often useful, but they lose their effect after a time. The carbonate of ammonium, to be useful, must be given often—five to ten grains (0.32 to 0.65 gm.) every two hours. The ammonium chlorid is indicated where less of a stimulating effect is necessary—5 to 15 grains (0.32 to 1 gm.) four times a day in combination with the syrup of squill in 15-minim (1 c. c.) doses, both in the compound licorice mixture. In some cases the iodid of potassium is very useful, especially when secretion is scanty. It should be kept up for some time. Among the more recent drugs recommended for chronic bronchitis is hydrastis canadensis in doses of 20 to 30 minims (1.25 to 1.85 c. c.) of the fluid extract four times daily. It is advised when there is muco-purulent expectoration, of which it changes the character and reduces the consistency with diminution of cough.

Inhalations of medicated vapors are sometimes useful. The compound tincture of benzoin may be thus used, also turpentine. They may be placed on the surface of boiling-hot water, the vapor from which will carry the medicated preparation with it, and may be conducted to the air-passages through a cone of paper placed over the vessel containing the medicament. These vapors are more efficient than atomized fluids. Simple steam or vapor from a two per cent. solution of common salt or of sodium bicarbonate may be used. If there is fetor, carbolic acid may be used in the atomizer, a two per cent. solution, or thymol one part in 1000.

Alkalinity is an essential condition of easy secretion from the air passages, so that both inhalations and internal remedies should fulfill this condition. Hence, simple liquor potassæ, U. S. P., in fifteen- to twenty-minim (1 c. c. to 1.25 c. c.) doses in milk is a good remedy. To this end the free use of alkaline mineral waters, as those of Vals, Vichy, and Ems, is useful.

Digitalis and strychnin are excellent medicines, especially the latter. Both stimulate the cardiac action and aid in pumping the blood through the lungs with increased force, thus causing relief to the congested mucous surfaces. Strychnin in ascending doses may be given with advantage.

As to *health resorts* suitable for cases of chronic bronchitis, those with a dry climate, not too cold, should be selected for cases with copious secretion, such as southern Georgia and the Carolinas or New Mexico in this country, or for stronger persons the cooler climate of Colorado. For cases of dry bronchitis the warmer moist climates of Florida are very suitable. In this, as in all other diseases, the factor of complete bodily and mental rest enters largely into the cure.

Chronic bronchial catarrhs always improve in summer, and it is generally sufficient if the patient be directed to leave the hot and noisome city and spend his summers either in the mountains or at the seaside, where the air is pure and bracing.

Of foreign resorts, those of southern Europe, especially Italy, the western Riviera, San Remo, Mentone, and Cannes, are suitable, while still better, if they can be availed of, are Egypt, Algiers, and the island of Madeira.

BRONCHIECTASIS, OR BRONCHIAL DILATATION.

Historical.—Laennec (1819) was the first to describe anatomically bronchial dilatation, and his admirable account remains at the present day the standard description of the condition. It should be mentioned, however, that Laennec himself tells how his attention was first called to it by Cayol, at that time a student, but afterward a professor of medicine, who was "astonished at finding a diseased state of the lung which up to that time had remained undescribed." This, according to Laennec, was in 1808. Laennec attributes the formation of bronchiectatic cavities to mechanical cause—viz., the pressure of bronchial secretion. Andral (1823) called into play disturbances of nutrition, and Reynaud (1835) the respiratory act.

Etiology.—The most common cause of bronchiectasis is chronic bronchitis, either simple or tubercular, the effect of the inflammation being to weaken the bronchial walls so that they yield to the inspiratory and expiratory strain to which they are subjected in the act of coughing. It is, therefore, often associated with emphysema. The same cause contributes to the bronchial dilatation following bronchopneumonia, measles, and whooping-cough in children. Accumulated secretion is also a factor, as seen in the dilated bronchi which succeed obstruction of a bronchial tube by a foreign body, or compression by aneurysm or mediastinal tumor. The traction associated with fibroid induration is also a cause of bronchial dilatation; hence we find it in association with interstitial pneumonia and sometimes in chronic pleurisy. Finally, bronchial dilatation is rarely a congenital defect, in which event it is also commonly unilateral and general—*bronchiectasis universalis* of Grawitz.

Morbid Anatomy.—Bronchial dilatation is cylindrical and sacculated. The terms explain themselves. Both forms may occur in the same lung.

In the *cylindrical* form, which is the more common, dilated tubes of nearly equal caliber may run through the substance of the lung, from the root to the pleural surface, producing an appearance not unlike the fingers of a glove. More frequently the smaller tubes only are affected, dilatation being recognized at autopsy by the inequality of lumen, rather than by *antemortem* physical signs. It may, however, be suspected in any case of chronic bronchitis with copious expectoration.

The *saccular* bronchiectases are spherical or oval dilatations, into which the tube merges gradually or suddenly. They may attain a diameter of from two to three inches (5 to 8 cm.), more or less. The lung tissue about a saccular dilatation is rarely normal. Commonly, the dilatations, single or multiple, are surrounded by indurated and contracted lung tissue, the traction of which on the bronchial wall produces the dilatation. Adhesion of the lung to the costal pleura also contributes, and large subpleural cysts are at times thus formed by the contracting tissue. The cavities thus produced are commonly at the base of the lung, while in chronic phthisis they are found at the apex. Cylindrical and saccular dilatation may also be associated under these circumstances. In universal bronchiectasis the entire bronchial tree is converted into a series of sacs communicating one with the other. Many cavities in pulmonary consumption are primarily bronchiectatic cavities.

In all forms there is decided change in the bronchial wall, the principal feature of which is atrophy. This atrophy not only attacks the mucous coat, but also the muscular, and sometimes the elastic tissue and cartilage, reducing the wall to a thin, smooth membrane, lined with pavement epithelium, instead of the usual cylindrical form. At times overgrowth, involving particularly the connective tissue, takes place, forming

lattice-like projections on the inner surface of the tube already referred to in treating of chronic bronchitis. At other times ulcerative processes develop, perforating the bronchus and invading the lung parenchyma, converting the bronchiectasis into an ulcerating cavity.

Symptoms.—These, in addition to those of the disease with which the bronchiectasis is associated, are the peculiar *sputum* and *paroxysmal cough*. The sputum furnishes the most distinctive feature, from which alone the diagnosis can sometimes be made. It is muco-purulent, of a dirty yellowish-green color and unpleasant, stale, and sweetish odor, though not exactly fetid, as in fetid bronchitis. It is often raised in mouthfuls—another characteristic. It also separates into layers, usually three, of which the upper is frothy and thin, the middle mucoid, and the lowest made up of pus and epithelium in various stages of fatty degeneration, acicular fat crystals, and sometimes red blood discs and hematoidin crystals sufficient to color it. Elastic tissue of the lung is not usually present; nor are tubercle bacilli, unless there is associated tuberculosis with ulceration of the bronchial walls.

The cough is paroxysmal, because it is not usually excited until the sac, which is often insensitive, becomes full enough to irritate the healthy mucous membrane, when cough is at once excited and continues until the cavity is empty. The paroxysms are usually in the morning, when they may be excited by a change in position. After their termination there is commonly a long period of rest until the sac—or a sac—is again filled. The more paroxysmal the cough and copious the expectoration in chronic bronchitis, the more likely is there to be a dilated bronchus. Very characteristic is the *absence of fever*.

Physical Signs.—When distinctively present, they are those of a cavity in the lung, readily recognizable when near enough to the surface. They include tympanitic percussion note, bronchial and even amphoric breathing, bronchophony or pectoriloquy if the cavity is empty. If it contains liquid, gurgling may be heard and the percussion note is dull. To palpation there is usually increased vocal fremitus, caused by surrounding consolidation. All signs vary according as the cavity is filled or emptied of secretion. A restricted breathing excursion may also be present, uninfluenced by the state of the cavity, whether full or empty.

Diagnosis.—A bronchiectatic cavity is usually distinguished from a *phthisical cavity* by the absence of tubercle bacilli and elastic tissue from the sputum of the former, the situation of the cavity in the center instead of at the apex of the lung, the history of its development, the absence of cachexia and fever. Hypertrophy of the right ventricle is more frequent in bronchiectasis, but may also be present in fibroid phthisis with or without bronchiectasis.

A *circumscribed empyema* which has ruptured into the lung is much more sudden in its development than bronchiectasis, while the history of a previous pleurisy is superadded. A coincident external perforation of an empyema would clear up all doubt. A true *abscess* of the lung which has found its way into a bronchus has also a different history of origin, succeeding, as it usually does, a pneumonia, a massive hemorrhage, or traumatic cause. The same is true of gangrene of the lung, which is, however, disclosed by the extreme fetor of the breath and expectoration.

Treatment.—This includes that of chronic and fetid bronchitis, to which may be added, under favorable circumstances, the injection of sacs and their drainage. It is to be remembered, however, that physical signs

are sometimes misleading, and that what seems to be the clearest evidence as to the exact site of a sac is not always to be relied upon. I well remember a case of my own in which there seemed to be the most conclusive evidence of the presence of a dilated bronchus below the angle of the left scapula—evidence satisfactory not merely to myself, but also to my colleagues, William Pepper and J. William White. At my request, Dr. White opened the thorax by exsecting parts of two ribs, when, to our astonishment, no cavity could be found by the cautious use of exploring needles. Prompt closure of the wound was followed by healing, and the patient lived for eight months.

The cure of well-established bronchiectasis is impossible, except, perhaps, in young persons. Something may be done to prolong life and make the patient more comfortable and less disagreeable to others. To this end we must aim at the evacuation and disinfection of the offensive purulent secretion, and as far as possible the obliteration of cavities. For the first of these, the inhalation of crude creasote vapor was recommended, first by Arnold Chaplin, and indorsed by Theodore Dyke Acland in an exhaustive paper on this subject. Intralaryngeal injections of oily and antiseptic substances have been employed, with doubtful results. The difficulties in the way of operation are shown in the first paragraph on treatment.

BRONCHIAL ASTHMA.

Definition.—Bronchial or spasmodic asthma is a paroxysmal asthma or a panting for breath, which is the direct result of a contraction of bronchial tubes.

Etiology.—There is some diversity of opinion as to the etiology of bronchial asthma. This much, however, is admitted, that in some way there is produced a narrowing of the smaller bronchi.

Various explanations of the narrowing are suggested. Some allege a simple swelling of the mucous membrane to be a cause. Such swelling is variously spoken of as “fluctionary” (Traube), “vasomotor turgescence” (Weber), “diffuse hyperemic swelling,” or “exudative” inflammatory swelling (Curschmann). On the whole, the older view of Trousseau, that the narrowing is due to a spasmodic contraction of the muscular coat, seems the most likely one, and has recently received the support of Biermer. Mention should be made of the theory of Wintrich and Bamberger that asthma consists in a tonic spasm of the diaphragm, a theory which Riegel has further developed by ascribing the spasm to a superexcitation of the phrenic nerve, resulting in a partially inhibited excursion of the diaphragm.

Accepting Trousseau's view of a primary spasmodic contraction of the bronchi, it becomes necessarily a reflex act, the causes of which are various. It implies, first, a hyperexcitability of the reflex center. Hence bronchial asthma is not infrequent in neurotic persons, and has even been classed as a functional nervous disease with neuralgia and epilepsy, with which it is said to alternate at times. Such hyperexcitability is sometimes inherited, so that bronchial asthma often runs in families. Presupposing such excitability, numerous peripheral causes may supervene, the most frequent of which is bronchitis. It very often happens that an asthmatic subject has an attack of asthma, brought on by “taking cold,” the incident bronchitis being the exciting event.

Comparatively modern studies have demonstrated the association of some affections of the throat and nasal passages with bronchial asthma, and that their removal has resulted in its cure. Among these have been enlarged tonsils, chronic catarrh, nasal polypi, and the like. Other causes in susceptible persons are impressions of certain odors, pleasant and unpleasant, notably that of flowers or plants in early summer, whence the term "rose" asthma and hay asthma, both of which are allied affections. A change of air, as from town to country, or the reverse, or from mountain to lowland, acts similarly. Causes more remote than those of the nasal passages, such as gastric derangement, intestinal worms, uterine disease, may be admitted. Purely emotional causes, as fright and emotion, may also act. The frequency of bronchial asthma in children has already been mentioned. It is more common in the male sex.

Morbid Anatomy.—Whatever may be the morbid state of the tubular structure of the lung during an attack of asthma, there are no post-mortem appearances which are distinctive of it. In the first place, the chance is seldom offered at the opportune moment, and I know of no report of a necropsy made on a person dying during an attack of asthma. In the case of the asthmatic dying at other times, there may be found the morbid states peculiar to chronic bronchitis and emphysema, but nothing more.

Symptoms.—The symptoms of an attack of spasmodic asthma are unmistakable. The typical asthmatic is apparently in good health between the attacks, and often is so up to the time of the attack, which then comes on suddenly, often at night. At other times there is a prodromal stage, a feeling of thoracic discomfort or "*tightness*" in the chest, or an anxious, nervous, restless feeling, the import of which is well understood by the victim.

The attack consists of a long-drawn-out inspiratory act, in which it is evident the air cannot get into the lung fast enough to meet the demands of the *besoin de respirer*. The auxiliary muscles of respiration, the sternocleidomastoid, and the scaleni, do their best to enlarge the thorax, but that is not the difficulty. It is the contracted tubes which resist the entrance of the air. Even more marked are the effort and the duration of expiration; hence the dyspnea is spoken of as an expiratory dyspnea. The abdominal muscles are the auxiliaries here, and they contract strongly and assume a board-like hardness. The air is heard to whistle as it enters and passes out of the chest. The patient sits in an upright position, or leans slightly forward, and often astride of a chair grasps the back with his hands, for it is by fixing the shoulders that he can bring the extraordinary muscles of respiration into play. His face is anxious, pale, or it may be cyanotic, and few more distressing pictures are seen. Notwithstanding his efforts, they fail of their purpose and comparatively little air enters the lungs. With all these efforts, the *breathing is not accelerated*,—at least accelerated to any marked degree,—while in a few instances the breathing-rate is diminished. The *temperature* is normal or subnormal, and the pulse is accelerated and small.

The attacks last for a variable period, rarely less than an hour, and unless broken up, sometimes several hours. They may *terminate* as suddenly as they began, sometimes with a spell of coughing. On the other hand, *cough is not a marked symptom*, and in brief paroxysms of asthma may be altogether wanting. In the severe ones, however, it is present, accompanied by a tough and scanty expectoration, containing rounded masses of matter, either yellowish or grayish translucent—the "*perles*" of Laennec. On

minute examination, these are found to be made up of the so-called Curschmann's spirals, together with numerous swollen and fatty degenerated pus-cells and cells shed by the bronchial mucous membrane and alveoli. The spirals have long been recognized, but were first studied by Ungar and Curschmann. They appear to be made up of *mucin* spirally arranged, entangling pus-cells and alveolar epithelium. A second form of Curschmann's spirals contains, in the inside of a tightly-wound spiral of mucin fibrils, another bright, clear filament. The spirals are believed by Curschmann to be formed in the finer bronchioles, and to be a product of bronchiolitis. Their spiral form is unexplained. The sputum also sometimes contains *crystals of calcium oxalate* and *calcium phosphate*. The yellow masses contain, in addition to the cells named, various numbers of acicular crystals, which were first found by Leyden in the sputum of asthmatic patients, and therefore called Leyden's crystals. They are identical with the so-called Charcot's crystals, found in leukemic spleen, bone-marrow, and semen.

In addition to the cases of typical asthma in patients perfectly comfortable between attacks, and for which the foregoing description is intended,

Fig. 48.—Curschmann's Spirals—(after Curschmann).
I, Natural size; II and III, enlarged; a, a, central thread.

patients with chronic bronchitis and emphysema are subject to attacks which may be called symptomatic asthma. The symptoms are, however, similar and need not be repeated. It is to be remembered, too, that emphysema is caused by asthma, as well as that chronic bronchitis and emphysema may cause asthma.

Physical Signs.—These are also characteristic. Inspection notes the most labored effort in breathing, yet the chest moves but slightly. It is in a state of permanent inflation. The spaces above and below the clavicle and above the sternum, the intercostal spaces, and the pit of the stomach are drawn in from the same cause—that is, the thoracic cavity not being filled from within, the external atmospheric pressure forces the yielding portions inward. Rhonchal fremitus is recognized by palpation, while vocal fremitus, obscured by the rhoncus, is further diminished by a frequently associated emphysema. Percussion is negative in uncomplicated asthma, but if asthma is associated with emphysema, it may produce abnormal resonance. Auscultation discovers the most striking and easiest recog-

nized of the physical signs. All over the chest are heard sonorous and sibilant râles, inspiratory and expiratory, the latter longer and more marked. In fact, for the most part, they do not require the ear to be placed close to the chest. They may be heard at a distance. The vesicular murmur, on the other hand, is inaudible. Later in the attack, as secretion increases, the râles become moist. It is to be remembered that chronic bronchitis, emphysema, and asthma may also complicate one another and render correspondingly complex the physical signs.

Diagnosis.—This can usually be made at a glance. *Spasm of the glottis* and *paralysis of the abductors of the glottis* produce similar efforts at breathing, but the dyspnea is inspiratory and unattended by the lung sounds characteristic of asthma, while the history will be found different. *Hysterical dyspnea* furnishes no physical signs, while in *cardiac asthma* also the breathing sounds are normal, or there is crepitation. (See also Cardiac Asthma.)

Prognosis.—Bronchial asthma, though a distressing disease, is not a fatal one. Very often the attacks grow more infrequent and milder as the patient grows older, and they may disappear altogether, while in some cases they increase in severity and frequency with age. In other cases a cure is effected by discovering and removing the cause.

Treatment.—The first object in the treatment of asthma is to *relieve* the *paroxysm*. This is best accomplished by a hypodermic injection of morphin, 1-4 grain (0.0165 gm.), with 1-150 grain (0.00044 gm.) of atropin, which may be repeated in an hour if ineffectual. If morphin is not at hand, nitrite of amyl may be inhaled from a handkerchief on which a few drops have been placed, or a pearl may be broken, if one of these be at hand. In the absence of amyl nitrite, chloroform or ether may be similarly used. After the paroxysm is broken, every effort should be made to *discover* a *cause* for the recurring attacks. The nose may be responsible, and should be carefully examined for any one of the causes referred to. Possible peripheral irritation, whether by error of diet, gastric derangement, uterine or other distant reflex cause, should be sought and corrected. These are not always easily found, but sometimes they are. Bronchitis, when present, also requires treatment by the usual remedies.

It is needless to say that when special external causes, such as odors or exhalations, or undiscoverable peculiarities of location are responsible, they should be eliminated. With all our efforts, however, the cause remains in perhaps a decided majority of cases undiscovered. But even under these circumstances we have in the iodid of *potassium* and *belladonna* two drugs which possess undoubted power to relieve bronchial asthma and even to avert attacks. A certain measure of relief is almost always secured by these drugs, and in many cases the effect is magical. From five to ten grains (0.33 to 0.65 gm.) of the iodid, and three to seven minims (0.2 to 0.5 c. c.) of the tincture of belladonna should be given every three hours until relief is permanent. Lobelia, formerly much used instead of belladonna, has fallen into disuse, probably on account of its disagreeable nauseous effect. The *fumes* of burning *paper impregnated with nitrate of potash* and *stramonium* are also useful adjuvants, and cigarettes and pastiles made out of such paper are constantly employed for their effect. These substances form the basis of most of the advertised remedies for asthma.

The *diet* of asthmatics should be exceedingly simple, as indiscretions in it are often the exciting causes of attacks. No fixed rules for climatic

treatment can be laid down, as conditions favorable to different cases are exceedingly capricious. On the whole, high, dry *climates* are most suitable for pure asthmatics,—*i. e.*, those cases uncomplicated with emphysema,—though moist, warm climates, such as those of Florida and Madeira and the Canary Islands, are also servicable, especially when there are catharrhal symptoms; or southern California, where the climate is also warm and equable, but drier. When there is emphysema, high altitudes are not well borne. Cold and moist climates are harmful. Oxygen breathing is often helpful, as is also inhalation of compressed air in the pneumatic cabinet.

PLASTIC OR FIBRINOUS BRONCHITIS.

Definition.—This is a rare form of inflammation of a part of the bronchial tree, commonly chronic, but occasionally acute, in which a fibrinous mold of the bronchus and its branches is formed and expelled. It does not include those instances which occur in connection with croup or diphtheria as an extension downward, or in pneumonia by centripetal extension.

Etiology.—No definite cause for this bronchitis is known, though it is frequently associated with tuberculosis—in ten out of twenty-one cases studied by Model. It occurs at all ages, and though more common between ten and thirty, has occurred at seventy-two. It has happened in more than one member of a family. It is found more commonly in males and in the spring months. Other associations named are probably accidental, as with skin diseases. In the chronic form, which consists in recurring attacks extending over many years, the same part of the bronchial tree is apparently attacked each time.

Morbid Anatomy.—As primarily expectorated, the exudate is a round mass mixed with blood and mucus. This mass, sometimes quite large, may be unrolled, when it is found to be a true cast, of dendritic shape and hollow interior, of the trunk and branches. The latter may even terminate in bulbous ends corresponding to the infundibula. The mold is true fibrillated fibrin, in which are embedded numerous leukocytes. It is whitish or yellowish-gray in color, and concentrically laminated. In the latter feature it differs from the branching clots, which occasionally form in a bronchus and branches after hemorrhage into the lungs. These are solid and homogeneous. A fine specimen of one of these is in the pathological museum of the University of Pennsylvania. The true fibrinous casts are usually 1 1-2 to 2 inches (3.75 to 5 cm.) long, but may be five or six inches (12.5 to 15 cm.) long. The tubes whence the casts come are not superficially changed, but on minute examination have been found bereft of epithelium. The submucous tissue may be swollen and infiltrated with serum. Charcot's crystals and Curschmann's spirals have occasionally been found.

Symptoms.—These are those of an ordinary bronchitis of severe form. There are aggravated *cough* and *dyspnea*. Sometimes this is preceded by a stage in which there is, for a variable time, prolonged, bronchial *catarrh* of ordinary severity. At times the attack is ushered in by *rigor*, and there are *high fever*, *pain* in the side, and *soreness*. There is *slight expectoration* until the cast is loosened and expelled. The cough preceding the expulsion does not usually last more than a few hours, though it does sometimes continue for days. With the expulsion of the cast comes prompt

relief for the time being. It is sometimes followed by slight *hemoptysis*, which may also rarely precede the expulsion. The expectoration of a single cast does not, however, terminate the attack. After twenty-four to forty-eight hours the cough and dyspnea return, and another cast is expelled. This may be kept up for several days, after which the attacks cease to recur. Smaller pieces may be expelled. The attacks may occur but once in a lifetime, or they may be repeated at intervals for years.

Physical Signs.—These are usually those of bronchitis. There is no dullness on percussion, unless it be from consolidation due to collapse of the lung. There may be, according to Walshe, circumscribed pneumonia with crepitant r le and rusty sputum. The effort at breathing is labored, and if there is obstruction of a large tubule, there may be retraction of the lower ribs during inspiration. The cast then begins to be loosened, and moist r les make their appearance.

Diagnosis.—The rarity of the disease is so great that in the absence of distinctive physical signs the true condition is rarely suspected. In recurring attacks the true nature of so severe an attack of bronchitis may be suspected.

Prognosis.—This is usually favorable, although the symptoms are often alarming. N. S. Davis has reported two fatal cases of the acute form.

Treatment.—The disease, so long as its true nature is undetermined, is treated as an ordinary bronchitis. If its true nature is suspected, the vapor from alkaline solutions should be inhaled, or these should be sprayed into the larynx. Lime-water is one of those commonly employed. Alkaline solutions may be of the strength of thirty grains (2 gm.) of sodium bicarbonate to the fluid ounce (30 c. c.) of water. Jaborandi or its active principle, pilocarpin, may be tried. Emetics should also be employed when the breathing is much embarrassed. They sometimes have the effect of discharging the cast. Iodid of potassium is recommended, and should certainly be used when the attack is protracted.

DISEASES OF THE LUNGS.

EMPHYSEMA OF THE LUNGS.

SYNONYMS.—*Alveolar Ectasia; Increase of Volume of the Lung.*

Definition.—There are two applications of the term emphysema, and they have very different significations. In the *first* place, there is *interlobular* or *interstitial* emphysema, in which, in consequence of rupture of air vesicles deep in the lung structure, the air escapes into the interlobular tissue and may collect there like rows of beads outlining the lobules, while under the pleura larger vesicles may form. This form occurs after wounds of the lung, and in severe and persistent whooping-cough, and in cough of bronchial asthma, in both of which the expiratory strain is very great. It is also termed acute emphysema. It is not, however, demonstrable clinically, except in those cases in which it takes place at the root of the lung and the air travels along the trachea until it reaches the subcutaneous tissue of the neck and chest-walls. It gives rise to a peculiar crepitation to the touch. A similar condition of the subcutaneous tissue may be due to infiltration of the tissues, with gas arising from decomposition. It is found

in the neighborhood of wounds which take on an unhealthy action, and where decomposition leads to the generation of gas. This form of emphysema is, of course, more circumscribed than that due to a wound of the lung.

The *second* form, *vesicular emphysema*, is an overdistention followed by atrophy of air vesicles, either symmetrical, involving both lungs, or localized. It occurs in certain portions of a lung adjacent to another which cannot, from some cause, expand fully in inspiration. Such are portions of the lung adjoining tubercular areas, or areas of collapsed lung, or adjacent to parts whose expansion is prevented by pleuritic adhesions. It is particularly the anterior parts of the lung that are the seat of localized emphysema in the latter case. When such complementary dilatation is impossible, as is often the case in extensive pleuritic adhesions, the chest-wall must sink in to occupy the space. Perhaps all emphysema is more or less localized, but in general or symmetrical emphysema very much larger areas of both lungs are involved. The distended air vesicles are useless, while many of them are also atrophied. The former is also called hypertrophic, but *pseudo-hypertrophic* would be a much more suitable term, because there is no true hypertrophic enlargement.

The term "compensatory" is also applied to localized emphysema, but this term should not be applied unless the dilatation is truly compensatory—that is, is the result of an effort on the part of a lung or portion of it to supplement the office of another more or less useless lung, when the condition is really developmental, and not degenerate.

A *third* form of emphysema of the lungs is known as *atrophic emphysema*; it is called also by Sir William Jenner *small-lunged emphysema*. In it the whole lung and thorax may be reduced in size, and even the respiratory muscles may be atrophied. It is a disease of old persons, and is to be regarded as an involution process. There is a true atrophy of air vesicles, and bullæ of various sizes are formed by the wasting of intermediate vesicles.

The section is limited to the consideration of

VESICULAR EMPHYSEMA—PSEUDO-HYPERTROPHIC EMPHYSEMA.

Etiology.—By far the larger number of cases of emphysema are the result of chronic bronchitis. This bronchitis may begin in childhood. It may begin as whooping-cough, from which the child has not completely recovered, or succeeding which it has been subject to constantly recurring attacks of acute bronchitis. It is scarcely likely, if the lung-tissue preserved its proper integrity, that even under the forced inspiratory strain of coughing the air vesicles would undergo the dilatation and destruction characteristic of emphysema. With chronic bronchitis there is sooner or later an impairment in the nutrition of the air vesicles, which makes them more yielding and more likely to give way under the strain. Blowing on wind instruments and glass-blowing, as well as occupations requiring muscular strain and the lifting of heavy weights, are assigned as causes. Bronchial asthma is another cause. In all these cases both inspiration and expiration co-operate to produce the strain, but it is probable that expiration is the more potent factor. The severe cough of chronic bronchitis begins with a deep inspiration which, while harmless to a healthy air vesicle, may overdistend a weak one. Then follow closure of the glottis and a forcible contraction of the muscles of expiration—abdominal muscles. The latter compress especially the lower part of the lung, and

as the air cannot escape, it is forced into the peripheral parts, overdistinging the air vesicles there. Again, the expiratory muscles compress the bronchioles more than the air vesicles, impede the exit of air from the latter, and thus overstrain them. So, also, in horn-blowing and muscular strain we have the effect of deep inspiration, and especially the increased pressure during expiration, with the glottis closed. We may admit also a valve-like effect of certain plugs of mucus, which permit the entrance of air during inspiration, but do not allow its exit. Thus, the vesicles become filled with air which cannot get out. Since the air is forced in the direction of least resistance, it is the air vesicles in the apices and edges of the lungs which dilate first. This is probably one way in which expiratory strain acts in producing dilatation. The valve-like action may also be in the opposite direction, permitting the air to get out of the vesicles, but preventing it from getting into them, and thus finally a portion of the lung becomes collapsed. The inspired air must go somewhere else, and produces what may be called a collateral dilatation.

I believe also that much public speaking and perhaps singing may lead to emphysema, especially as the speaker grows older, because the lung is held inflated a longer time than in ordinary speaking.

The vesicles thus overdistinged finally lose their elasticity, like an overdistinged india-rubber air balloon, which, after repeated distentions, loses its power to recoil. Succeeding the overdilatation comes atrophy of the vesicles, and with this the blood-vessels surrounding them are destroyed. Although under these circumstances the lung occupies more space, its blood-aërating power is diminished. The circulation is cut down to the larger trunks, and the blood takes a short cut, as it were, from the pulmonary arteries to the pulmonary veins. The aëration of the blood is thus rendered difficult or impossible, accounting in part for the dyspnea.

There is also reason to believe that heredity plays a decided rôle in the causation of emphysema, and that congenital defect often takes the place of acquired nutritive retrogression. This was first shown by the late James Jackson, of Boston, who found that in eighteen out of twenty-eight cases one or both parents were affected. Accordingly, too, emphysema is surprisingly common in children, and in adults may often be traced back to childhood.

Morbid Anatomy.—The emphysematous chest is often highly characteristic, in that the anteroposterior diameter is greatly increased, making the two diameters nearly or quite equal, producing the "barrel shape." On opening the thorax in an adult the cartilages are found calcified, and on raising the sternum the greater volume of the lungs at once shows itself. They are in a state of permanent inspiration, meeting by their edges in the mediastinal space and almost or entirely covering the pericardium. Nor do they collapse when removed from the chest.

The individual air vesicles are not only dilated, but large numbers of them are atrophied, producing bullæ of various sizes, from the walls of which extend inward edges which are the remnants of vesicles, so that the large vesicle has been aptly compared to a frog's lung with its semipartitions. The pleura is pale and the lungs are especially so, partly from atrophy of the pulmonary capillaries which accompanies the destruction of the vesicles, associated with diminution in the natural pigment. The lung surface pits readily on pressure. The distention and destruction are not limited to the periphery of the lungs, but are also found in the center and toward the root, where large bullæ, two to three inches (5 to 8 cm.) in diameter, may be found.

The bronchi exhibit the changes already described under Chronic

Bronchitis and Bronchiectasis. An important anatomical change, not usually demonstrable before death because of the voluminous lungs, is *hypertrophy of the right ventricle of the heart*, due to the extra effort required to drive the blood through the diminished vascular area in the lungs. In the later stages the hypertrophy has given way to dilatation, and there may be relative insufficiency of the tricuspid valve with dilatation also of the right auricle. In a few cases there is hypertrophy of the whole heart. There is sometimes, also, atheroma of the pulmonary artery and of the other blood-vessels, or there may be associated pulmonary tuberculosis of the fibroid variety, as well as Bright's disease.

Symptoms.—The typical emphysematous subject may often be recognized by his peculiar *round-shouldered stoop* and *barrel-shaped chest*. Rarely, this form of emphysema is an acute or comparatively rapid development, succeeding whooping-cough; but the approach of the disease is mostly gradual, the first symptom to develop and remain constant being *shortness of breath*, which is partly due to the fact that the air in the vesicles does not undergo the usual interchange. In health the intercostal muscles, the diaphragm, and auxiliary muscles of respiration enlarge the thoracic box, and the lungs expand to fill it partly by their own resiliency, but chiefly to fill the vacuum, producing the act of inspiration, while the air is expelled in expiration partly by the recoil of the elastic tissue and partly by the pressure of the contracting thorax. This natural resiliency is absent in a large degree, while the thoracic box also remains in a state of "rigid dilatation." The lung is always filled with air, but it is air charged with carbonic acid and does not change. As a consequence the patient makes increased efforts to draw the air into the lungs, but as the air vesicles are already filled, these efforts are ineffectual. The *dyspnea*, which is but slight at first and is brought about only by exertion, soon becomes decided and constant. The *pulse-rate* is also accelerated, but the temperature is usually normal. *Cyanosis* is a characteristic symptom in established cases, owing to the universal presence of unaërated blood.

Aside from these symptoms are mainly those of the associated bronchitis,—viz., *cough*, *expectoration*, and sometimes *oppression*,—while variations in these add to or abate his discomfort. With failure of the right heart come venous engorgement, dropsy, and effusions into the serous sacs. Tuberculosis of the fibroid type sometimes develops.

Physical Signs.—The physical signs are not always distinctive. Inspection reveals a rounded chest, with increased circumference and wide intercostal spaces in the hypochondriac regions, but narrow above. The epigastric angle is obtuse. The result is the well-known "barrel-shaped" chest. More rarely the emphysema may be so circumscribed as to produce local bulging, by preference over the upper lobe of the right and lower lobe of the left lung. Expansion of the chest-wall is diminished, while the scaleni and sternocleidomastoid muscles stand out distinctly. The chest does not expand, but is raised up by these muscles, which are hypertrophied; the apex-beat is not visible, but may be felt displaced downward and to the right, and is often difficult to find, because covered up by the enlarged lung. The breathing is rapid. There may be retraction of the lower intercostal spaces and the upper abdomen instead of swelling out during inspiration, because of failure of the diaphragm to descend. Vocal fremitus is diminished, while the natural resiliency of the chest-walls is substituted by increased resistance.

Percussion produces resonance exaggerated in various degrees, some-

times amounting almost to tympany, the result of the overdistention of the air vesicles, whose elasticity is spent. To auscultation vocal resonance is decreased because of the diminished vibration in the air columns. Feeble crackling is sometimes heard. Strümpell says the vesicular murmur is at times exaggerated and "shuffling," at others "rougher and more indefinite." Roughness and exaggeration seem impossible in true emphysematous areas. They may be present in adjacent supplementally acting areas. If bronchitis is present, its sounds are associated, and often obscure all else. The pulmonary second sound at the second left interspace is accentuated on account of the hypertrophy of the right ventricle, but the heart-sounds are usually obscured by the extra covering of the lung. With dilatation of the right ventricle, which sooner or later succeeds, the increased accentuation disappears.

Interlobular emphysema, in which the connective tissue between the lobules is infiltrated with air as the result of rupture of air vesicles caused by violent acts of coughing or by wounds of the lung, affords no physical signs, or rarely any symptoms. The shape of the chest in such cases is not altered. Suddenness of onset is characteristic of this form of emphysema, and it is apt to be associated with a similar infiltration of the tissues of the neck, which gives rise to a very distinctive crepitation on palpation.

Diagnosis.—This is not usually difficult, at least in true symmetrical emphysema. In *pneumothorax* there is some simulation of the symptoms of emphysema. There is the same shortness of breath, and there is some resemblance in the physical signs. There is bulging of the chest, which is, however, more marked on one side than on the other. On the other hand, it is rather rare to have a uniform symmetrical emphysema, and we may have here also a greater prominence of one side than of the other. Thus, the parts of the chest more likely to be affected with emphysema are the upper part of the right lung and the lower part of the left. Also in the matter of percussion, both emphysema and pneumothorax give hyperresonance. Pneumothorax, however, gives more marked tympany than emphysema. It has always seemed to me that the clearness of resonance found in emphysema has been exaggerated in the text-books. The hyperresonance, although often marked, is not always so. The unyielding chest-walls modify it. The hyperresonance of pneumothorax is a real tympany, comparable to that obtained over the distended abdomen. In both, the thickness of the chest-walls exerts a modifying effect. Metallic tinkling is a distinctive sign of pneumothorax, caused by the dropping of fluid from the perforated lung into the air-resounding pleural sac. In the lower portion of the chest with pneumothorax there is always effusion, which gives flatness on percussion, and a line of separation between tympany and flatness is demonstrable. Pneumothorax is sudden in its occurrence, whereas emphysema develops gradually. It is, however, not impossible for the two affections to be combined.

There is still another condition with which emphysema may be confounded, though it is of rare occurrence; I refer to *diaphragmatic hernia*, in which tympanitic resonance is a striking symptom. I had under my observation for a long time a very singular case, in which there had been a sudden development of symptoms. The condition came on suddenly, while the patient, a man, was engaged in a scrimmage or wrestle. He was seized with a sudden sharp pain in his left side, and a day or two later began to have a peculiar puffing respiration. With this there was extraordinary clearness on percussion over the region of the left lung. He was examined repeatedly by

myself and others, but no one thought of the true cause—none suspected diaphragmatic hernia. Acute emphysema was thought of. The autopsy showed that almost one-half of the abdominal viscera was in the pleural cavity, and that the lung was pushed into the upper portion of the chest, occupying a space about the size of the fist. This man presented the bulging, the shortness of breath, and the hyperresonance peculiar to emphysema.

The *Skodaic hyperresonance*—resonance above a pleural effusion—also resembles that of emphysema, but attention to the history and physical signs other than resonance will discover the true cause of the resonance.

Prognosis.—This, except in cases of acute emphysema, which heals spontaneously, is unfavorable as to cure. The course is, however, always a chronic one, and much may be done for the comfort of the patient. No classes of cases are so benefited by admission into hospitals as members of the laboring class afflicted with emphysema.

Treatment.—It is impossible, so far as we know, to restore destroyed lung texture. If a number of air vesicles have been converted into one sac or bladder-like cavity, there are no means by which these vesicles can be restored. At the same time, when the patient is young, there is some hope of cure if the structural loss is not too great. Effort must be directed mainly to averting those conditions which complicate and increase the emphysema. As I have said, chronic bronchitis is its most frequent cause, and, therefore, we must try to relieve this condition by every means in our power. As the general health is often impaired, it is as important that this should be re-established as that the bronchitis should be relieved. The blood is to be restored to a proper composition by tonic remedies, like cod-liver oil and iron, and the very best food that the patient can procure. To the cod-liver oil and iron should be added strychnin in full doses, 1-30 to 1-12 grain (0.0022 to 0.0027 gm.), while arsenic is an admirable tonic either in the shape of Fowler's solution, five drops at a dose for an adult, or of arsenious acid, 1-30 grain (0.0022 gm.).

While the bronchitis is treated by the usual remedies, it is of the utmost importance that the stomach should be kept in good condition, and that digestion should not be interfered with, while more than ordinary care is required in the selection of remedies for the bronchitis. A very useful measure in these cases is counterirritation, which in no way interferes with digestion. This may be applied in various ways; blisters, iodine, and mustard may be used. A mustard plaster can be so prepared that it may be worn continuously without discomfort—taking mustard and flour in the proportion of one to five, and using equal parts of the white of an egg and glycerin with which to mix it instead of water.

Strychnin is an admirable remedy, not only as a tonic, but it may also be regarded as an expectorant, and secretions in the lungs are often disposed of by its use. It has also the effect of improving the nutrition of the muscular tissue of the walls of the bronchi, as it has of improving the muscular tissue in general. Full doses should be given—not less than 1-30 grain (0.002 gm.) three times a day, increased gradually to 1-12 grain (0.0055 gm.). This is to be kept up for a long time.

Bronchial asthma is one of the most serious and frequent complications, and often overshadows all else. There is no more efficient means of breaking up such an attack than the hypodermic injection of 1-4 grain (0.0165 gm.) of morphin with 1-120 grain (0.00055 gm.) of atropin. This will usually relieve the paroxysm almost immediately. If relief is not complete, the

injection may be repeated and renewed every six hours. The various inhalations employed for asthma may be used, such as the smoke of burning stramonium or tobacco, ether, chloroform, and amyl nitrite. Of course, in connection with the attacks of asthma the other remedies of service in relaxing spasm, such as belladonna and iodid of potassium, may be given. Tincture of belladonna in doses of five to ten minims (0.31 to 0.62 c. c.) combined with ten grains (0.66 gm.) of iodid of potassium will break up so much of this condition as is due to spasmodic contraction of the tubules.

To relieve the constant dyspnea, the treatment suggested some years ago by Waldenburg is one the usefulness of which is only limited by its relative difficulty in application and the costliness of the necessary apparatus. It consists in the inspiration of compressed air and the expiration into rarefied air. It is evident that if compressed air can be introduced into the vesicles, the aëration of the blood will be more perfect, and that if the patient breathe into rarefied air, the residual air, which it is so difficult to get rid of, will be more effectually sucked out. The compressed-air chamber has a similar purpose.

Expiration may also be aided by compression of the chest, intermittently applied so as to coincide with natural breathing. This must usually be practiced by a nurse or an attendant, but Strümpell describes in his text-book a simple contrivance devised by a patient of his own for self-treatment. It consists of two boards fastened behind and allowed to project forward on each side in front, so that the patient himself, taking hold of the projecting ends, can compress his own chest with each act of expiration.

TUMORS OF THE LUNG.

The lungs are subject to morbid growths classified as tumors, though, owing to their situation, they rarely present the macroscopic, tumor-like qualities.

They include carcinoma, and many of the histioid tumors.

Etiology and Morbid Anatomy.—*Carcinoma* occurs rarely as a primary growth, but is not infrequent as a secondary new formation. Primary cancer presents itself usually in the shape of a white or yellowish nodule two to four inches (5 to 10 cm.) in diameter. It is found in the upper lobe of one lung, posteriorly and externally; more seldom in other parts. It probably originates in the alveolar epithelium, and causes secondary infiltration of the bronchial glands and pleura. It may be represented by any of the three principal forms, scirrhus, encephaloid, or epitheliomatous, also by colloid and melanotic. It occasions a reactive pneumonia in the lung tissue about it, and often furnishes the physical signs of this affection.

There also occurs in the lung a primary *peribronchial* cancer, disseminated in nodules throughout the lung along the bronchi, smaller nodules on the smaller bronchi, and larger, irregular masses on the larger, varying in size from that of a pea to a walnut. It produces also infiltration of the lymph glands at the root of the lung. *Sarcoma* is also a rare form of primary tumor of the lung.

More frequently both carcinoma and sarcoma are found in the shape of secondary nodules invading both lungs. From three to twenty opaque white nodules, 1-2 inch (1.25 cm.), more or less, in diameter, are found

irregularly scattered through each lung. Every variety of primary cancer may be thus represented secondarily in the lung. Its origin is probably embolic, and it may be secondary to cancer elsewhere, most frequently in the breast.

As elsewhere, these growths generally present themselves after middle life, primary cancer affecting either sex about equally, while secondary is more common in women, consistently with the more frequent occurrence of cancer elsewhere in women.

The histioid tumors are represented by a subpleural enchondroma, occurring, rarely, primarily as large as a walnut; more frequently, secondary to occurrence elsewhere, when it may attain a large size. Other histioid tumors are myxoma, adenocarcinoma, dermoid cysts, hydatid cysts, fibromata, osteomata, and gummy tumors.

Symptoms.—Carcinoma and sarcoma may both be latent, or at most produce such vague symptoms that it does not occur to physician or patient to locate them. There may, however, be *pain, oppression, cough, expectoration*, and superficial signs of *vascular obstruction*, such as lividity of the face and swelling of the upper extremities. The encroachment of the larger cancerous masses upon the pleural cavity may be marked. Pressure on the trachea and bronchi may occur and occasion great *dyspnea*, while the heart may be dislocated. The pneumogastric and recurrent laryngeal nerves are sometimes involved, occasioning the various forms of paralysis of the vocal cords and aphonia. The reactive pneumonia referred to may present the physical signs distinctive of this disease, and it is probably thus that the prune-juice expectoration, thought to be quite characteristic of cancer of the lung—ten times out of eighteen, as elaborated by Stokes many years ago,—originates. This complication, too, may occasion the fever which is sometimes present.

The external lymphatic glands, as those in the neighborhood of the clavicle, may be involved and exhibit enlargement.

Sooner or later, if the patient lives long enough,—that is, if his life is not destroyed by some encroachment on the breathing or vascular function,—he emaciates, and becomes cachectic and debilitated. The more usual duration of the disease is from six, to eight months, but death is liable to occur suddenly from the causes named.

Physical Signs.—These, of course, are indefinite, and it is probably their indefinite and irregular manifestation, with the symptoms named, which will suggest the nature of their cause. Physical signs of pneumonia and pleurisy, either alone or combined, may be present, the voice and breathing sounds and percussion note being affected accordingly.

Diagnosis.—This, in the case of primary cancer elsewhere, is suggested whenever any of the symptoms named occur in a pronounced degree and are sufficiently long continued. In the case of primary growths, the diagnosis must longer remain doubtful, and we must study and await the development of the more distinctive symptoms.

The non-malignant tumors present no signs by which they can be distinguished from the malignant, except that their course is less rapid and they develop no cachexia.

Treatment.—This consists only in measures calculated to relieve symptoms and to make the patient comfortable.

DISEASES OF THE PLEURA.

ACUTE PLEURISY.

Definition.—Acute inflammation of the serous investment of the lung or of its reflection on the ribs and diaphragm.

Etiology.—I still believe that pleurisy may be caused by simple chilling of the body during exposure to cold, in other words, that not every pleurisy is a tubercular pleurisy. Doubtless more cases are tubercular than was formerly supposed, but it does not seem likely that the large number, exhibiting the physical signs of pleurisy, from which recovery is apparently complete, can originate in this way. At the same time it must be admitted that the proportion of cases which are tubercular in origin is very much larger than was at one time supposed, and, moreover, that many cases of tuberculosis supposed to have succeeded upon pleurisy have really been primary tubercular pleurisy.

The conclusions of a very important paper read by Richard C. Cabot before the Association of American Physicians in May, 1902* may be said to be the most recent expression of our knowledge:

1. Eighty per cent. of the cases of uncomplicated serous pleurisy are in good health after five years or more (more than half of these have been followed for ten years or more).

2. Ninety per cent. are apparently in full health at the end of from two to five years—that is, the pleurisy had no immediate connection with any other affection.

3. Fifteen per cent. of the cases have sooner or later developed demonstrable tuberculosis of lung or bone, but in only three per cent. has this tuberculosis manifested itself within two years of the date of pleural effusion.

4. The type of tuberculosis which occurred in these cases was, as a rule, mild and of slow course. Death did not occur until five years or more after the pleurisy in one-half of the 23 cases which developed obvious tuberculosis. Six of the 23 are still alive, despite the tuberculosis, after periods of ten, nine, six, four, two, and one year.

5. Nevertheless, a very rapid form of tuberculosis may develop many years after the pleurisy—nine years and sixteen years, respectively, in two cases of this series—so that the patient is never safe from the possibility of death from tuberculosis merely because his pleurisy lies ten or fifteen years behind him.

6. A study of the clinical records of the whole group of patients under consideration shows that among those who have remained in perfect health for five years or more only 25 per cent. had any family history or past history of tuberculosis, while of those who have become tuberculous 67 per cent. had tuberculosis in their immediate family or in their own past history. A careful history, therefore, is of great importance in the prognosis of pleural effusion. On the other hand, the physical signs during the course and convalescence of the pleurisy were not markedly different in the group of cases in which tuberculosis later developed from the signs in those who have remained well.

7. Recurrence of the pleurisy itself in patients who have recovered from the original attack occurred in only five cases, or 3 per cent. of this series.

* "Transactions of the Association of American Physicians," vol. xvii., 1902, p. 156.

Reaccumulation of the fluid immediately after tapping is rare, occurring in only two cases, or 1.3 per cent.

8. Among the 14 patients who, after recovering from the pleurisy, died of some other disease not one developed any disease which could reasonably be considered a result of the pleurisy—the causes of death were alcoholism, hepatic cancer, dysentery, pulmonary embolism, mitral stenosis, aortic regurgitation, chronic nephritis (3), cerebral hemorrhage, measles, pneumonia (3).

9. Finally, no attempt was made to discover what percentage of this whole group of cases is due to tuberculosis. So far as the statistics go the cases may be all of tuberculous origin.

What his figures do tend to prove is that whether pleurisy means tuberculosis or not, the outlook is bright, provided no family history of tuberculosis clouds it. If pleurisy means tuberculosis, it is a very mild form of tuberculosis and one from which recovery is usually complete under proper treatment.

In addition to tuberculosis as a primary cause of pleurisy we must mention rheumatism and chronic Bright's disease as predisposing causes, at least. It should be said, also, of the latter that a certain proportion of them have been relegated to the tubercular pleurisies. The pleurisies which go to make up the sum of the phenomena of pyemia are of undoubted microbic origin. If rheumatism be microbic, then, too, the pleurisies which occur secondary to it must, of course, be referred to the same category. In addition to these instances of primary and secondary pleurisy must be mentioned those which are the result of extension of inflammation by continuity and contiguity, as from the adjacent lung to the pleura over it or from the diaphragm to the pleura above it; also pleurisies of traumatic origin.

Morbid Anatomy.—The morbid anatomy of pleurisy will be best understood by supposing every pleurisy to begin, as it probably does, with a dry stage, a *pleuritis sicca*, whatever may be its subsequent course. Thus considered, the earliest stage of all pleurisies has a hyperemic basis, succeeded immediately by a roughness of surface due to loosening and detachment of the epithelium, a roughness increased by the addition of fresh inflammatory lymph composed of transuded fibrin and wandered-out leukocytes from the subpleural blood-vessels. Further progress of such pleurisy is—

First, toward *resolution*, in the course of which the product described liquefies and is reabsorbed.

Second, toward *organization* and *adhesion*, in which vascularization and fibrillation take place and the two surfaces of the pleura are more or less permanently glued together over an area corresponding to that of inflammation. This is the probable explanation of the little patches of adhesion so frequently found at autopsies, some of which may have formed without the consciousness or discomfort of the patient, while others have succeeded upon a "stitch" in the side which has been passed by as of little consequence. Other instances of this primary adhesive inflammation are found between the opposed surfaces of pleural membrane covering tubercular deposits in the lung, or limited pneumonic areas, or morbid growths, such as gummy tumors, cancers, and sarcomata.

Third, toward *serous accumulation* constituting *exudative pleurisy*, in which varying quantities of fluid are transuded into the pleural cavity. In

this usually clear, straw-colored exudate may be suspended shreds of the yellowish plastic lymph already described, which accumulates also most abundantly where the movement of the pleural surfaces is least, as in the chinks and corners of the pleural cavity. This effusion also, in a large number of cases, is absorbed, allowing the pleural surfaces to approach each other and again unite by what is known as secondary adhesive inflammation, organization taking place as before, producing either continuous fusion or bands of new tissue attaching different parts of the pleural surface. The question as to how the process of exudation is stopped is an interesting one, which cannot be satisfactorily answered, though it is probable that pressure of accumulated fluid and contraction incident to organization, as well as cessation of the cause, may be a part.

The ordinary serous fluid which commonly fills the sac in sero-fibrinous pleurisy is a highly albuminous liquid, sometimes coagulating spontaneously, in which may be found a few leukocytes, exfoliated endothelial cells, shreds of fibrin, and sometimes a few red blood discs. Modifications are those in which the red blood-corpuscles are much increased, producing a bloody fluid, or in which leukocytes are variously numerous, short of a number sufficient to justify the term *pus*. Urea, uric acid, and sugar are sometimes found in pleural exudates. The quantity of fluid ranges from half a liter to four liters (1 pint to 4 quarts).

Fourth, toward *pus-formation*, in which either primarily, from the outset, or secondarily,—that is, some time after the process has commenced,—the microbes of suppuration become active, and produce a purulent product or an empyema. The onset of this wandering out of numberless colorless cells is often announced by a *chill*. Even such an accumulation of *pus* may in rare instances disappear without active interference, permitting the approximation and union of the two pleural surfaces. The pleural surfaces thus apposed are, however, comparable to an ulcer, and the union and repair take place by formation of cicatricial tissue. This is subject to the contraction usual to such tissue, dragging not only the heart and lungs out of place, but also in extreme cases the ribs and vertebræ, producing slight lateral curvature of the spine.

Various displacements of adjacent organs are caused by the liquid effusion. In right-sided pleurisy the liver is depressed. A very striking case came under my notice, in which the liver was pushed so far forward and downward as to produce the appearance of an abdominal tumor to the left of the epigastrium. In left-sided pleurisy the heart may be displaced so far that the apex will be to the right of the sternum. The displacements from traction after organization are difficult to describe, but the heart may be dragged so that its apex is much higher than is normal or further to the right, while the parts of lung adherent are drawn in various directions, with the production, at times, of bronchiectatic cavities. If the patient die while large liquid effusions are present, the lung is also found compressed into the back part of the pleural sac.

Symptoms.—The initial symptom of pleurisy is usually *pain*—at first in the side. It may, however, be preceded by a *chill*, and at times there may be a short *prodrome of discomfort* in no way peculiar. The pain in bad cases is of the severest kind, and among the pains most difficult to relieve. It is sharp and cutting in character, aggravated by breathing, so that the patient takes the shortest breath possible, and the breathing is made up of short, hurried gasps. Cough likewise causes agonizing pain, and it is

accordingly restrained. Nor is the pain in these cases always confined to the chest, but may shoot down into the abdomen and back. The latter probably implies that the diaphragmatic pleura is involved. *Fever* is also a constant symptom, but is not, as a rule, so high as in pneumonia. At the beginning the temperature may be 102° or 103° F. (38.9° or 39.4° C.), but it subsides early, even though the other symptoms abate but partially, and under any circumstances it falls much lower after a week or ten days unless there is purulent exudate, when the fever assumes a hectic type. The *cough* is peculiar enough to require special mention. It is a short cough, attended with little expectoration, and is a much less conspicuous feature than in pneumonia. Its characteristic shortness is due to the pain caused by the act of coughing, on account of which the act is cut short. The *decubitus* of pleurisy is quite constantly on the affected side, in order that the unaffected side may be free to expand. The patient also has less pain when he lies on the affected side, because the range of its motion is restricted. This pertains to pleurisies associated with copious effusions, as well as dry pleurisies.

While the majority of pleurisies begin in this way, a certain number also begin insidiously. For days and even weeks the patient, while feeling uncomfortable and doubtless feverish and slightly dyspneic, continues his occupation, and even when the physician is called, scarcely mentions symptoms which suggest an examination of the thorax. Such pleurisies are known as *latent* pleurisies. They are latent only to superficial observation. Closer investigation promptly reveals the physical signs of a pleural effusion.

It has already been mentioned that purulent pleurisies may be primary or secondary. In any event, they are most frequently tubercular, and an examination of the pus from such a pleurisy not infrequently discovers the tubercle bacillus in it.

Physical Signs.—Acute pleurisy is also resolvable clinically into three stages, each of which is characterized by physical signs more or less distinctive. They include a dry stage, a stage of effusion, and a stage of resolution or absorption.

The *first* or *dry stage* is characterized anatomically by the presence of the so-called lymph or exudate on the pleural surfaces. During this is revealed to inspection a restrained expansion of the affected side, often thrown into jerks or catches because of the pain suffered in a continuous inspiration. The expansion on the opposite side is full and unhampered. The patient lies on the affected side. Palpation may recognize a fremitus corresponding to the friction of the two pleural surfaces. Percussion in this stage is negative, except that it may cause pain, but auscultation recognizes the friction sound, which will be further characterized in treating diagnosis. It may be at a single spot in the inframammary or infra-axillary space, and hence be overlooked. At other times it may be noted over a considerable area. According as the inflammatory process stops here with resolution or continues into the second or stage of effusion, there may or may not be other signs.

The signs of the *second stage* vary with the amount of liquid in the sac; with a small amount the lungs are slightly floated up, and there may be no signs, unless it be a vesiculotympany above the line of the fluid, a Skodaic resonance by mediate relaxation of the air vesicles. The effusion, however, rarely remains so trifling, but commonly rises to the midchest. In the

upright position of the patient inspection recognizes in a spare person shallowness and perhaps obliteration of the lower intercostal spaces. The motion of the chest-wall is lessened both in the vertical and transverse directions.

To palpation vocal fremitus is diminished over the area of effusion, but may be increased in the lung above it. To percussion there is absolute flatness over the area of effusion, but the line of demarcation is not everywhere at the same level, being higher behind than in front. The late Calvin Ellis first called attention to an **S**-like curve in the line of demarcation which is said to be diagnostic. Very important in the diagnosis is the fact that the fluid changes its level when the position of the patient is changed, and correspondingly the line of dullness is altered. There is also an abnormal sense of resistance to the finger in percussing over the area of effusion. Above the effusion, especially anteriorly, there is again Skodaic resonance by mediate relaxation, and even rarely a "cracked-pot" sound. Tympany may also be due to the proximity of a distended stomach. Measurement discovers that the circumference of the affected side is a centimeter (0.4 in.) or more greater than that of the other side.

To auscultation the breathing sounds are inaudible or very feeble, as compared to the corresponding portion of the opposite side, but vocal resonance, though diminished, is still distinctly heard where the collection of fluid is moderate. Above the line of dullness there is occasionally a friction sound, and close to the root of the lung bronchial breathing may be heard. This is, however, more apt to be the case when the effusion is larger and the lung is further compressed. Egophony is also sometimes heard.

When the effusion is larger, filling up two-thirds or three-fourths of the pleural sac, the effects described are increased, while new ones are added. Inspection notes that respiratory movement is still more hampered, that the intercostal spaces are widened and even bulging, while fluctuation may sometimes be recognized through them. The heart is displaced by the accumulated fluid, and if the fluid be in the left sac, the apex is often found far over to the right of the median line, and if in the right, the apex may be pushed further to the left. The heart-sounds are not, however, altered. On the opposite side the breathing movements are supplementally increased. There is complete absence of vocal fremitus on the affected side.

Percussion is absolutely flat all over the effusion, and Skodaic resonance is not now obtainable, because the lung is too thoroughly compressed up into the apex of the sac. Resistance to pressure is marked. On auscultation bronchial breathing may be heard at the upper posterior portion of the lung, because the large tubes are still pervious to air, and the compressed lung intensifies the sound. Sometimes bronchial breathing is heard in more peripheral parts of the chest, probably conducted hither along a band of adhesion or along a rib. Elsewhere there is absence of breath-sounds. Vocal resonance and whispering voice are alike absent, or the former is very feeble. In certain situations, too, high up, where there is but a thin film between the chest-wall and the lung, there may be egophony, but this is more likely to be present as the fluid is being absorbed.

In the *third stage*, if resolution takes place with a gradual retrocession of the fluid and the re-expansion of the lung, we have a return to normal physical signs. There may be, too, a *friction redux*. A considerable time is, however, required for absorption, and it is often many days before the normal breathing sounds are heard with their usual intensity or the natural fremitus is felt. Often, on the other hand, resolution is not complete, and

the two surfaces become glued together, constituting a *plastic pleurisy*, and the feebly-heard breathing sounds and diminished fremitus and vocal resonance remain more or less permanent (chronic pleurisy). There then remain the symptoms and sequelæ of a chronic pleurisy. In cases of purulent pleurisies, if recovery takes place it is always by adhesion of the apposed surfaces. (See Chronic Pleurisy.)

In connection with the heart, *pleuropericardial friction* may be heard if the pleura covering the portion of the lung adjacent to the pericardium is involved. The apex-beat may not be discoverable if it is so dislocated as to be covered by the sternum, and it often happens that the heart must be located by its signs.

Varieties of Acute Pleurisy.—*Tubercular pleurisy* is a pleurisy due to the invasion of the pleura by the tubercle bacillus, and has been considered when treating of tuberculosis.

Diaphragmatic pleurisy is a painful form of pleurisy, in which the pleural covering of the diaphragm is involved, either alone or along with the remaining pleura. It is usually dry, plastic, but may also be exudative, with a serofibrinous or purulent product. The pain is low down in the thorax in the zone of the diaphragm, and is often aggravated by deglutition as well as by breathing. Because of the pain in breathing, the diaphragm is fixed and the patient breathes by the upper thorax. Of diagnostic value is the fact that the pain may be increased by pressure at the insertion of the diaphragm at the tenth rib.

Hemorrhagic pleurisy, characterized by bloody effusion, is found in asthenic states, however induced, in tubercular pleurisy, in which event the hemorrhage occurs from the young blood-vessels, and in cancerous pleurisy; also sometimes in persons otherwise healthy. It is, of course, not to be confounded with blood-stained serum, caused by wounding a blood-vessel in the act of tapping or with a hematothorax from rupture of an aneurysm.

Encysted or circumscribed pleurisy is a form of purulent pleurisy in which adhesions form so as to produce loculi, or spaces which are filled with pus. They are quite difficult to recognize during life—in fact, they are commonly found when exploring the chest with the needle. More rarely they are revealed to physical examination, dull percussion areas being found in alternation with clear areas. Such physical signs should suggest the use of the needle to clear up the diagnosis. These collections sometimes pulsate and become *pulsating pleurisies*. Pulsating pleurisies are almost invariably on the left side and receive in some way the impulse of the heart, which in turn is communicated to the eye or hand of the observer. The possible confounding of these with aneurysm will be again referred to.

In *interlobular pleurisy* the apposed surfaces of two lobes of the lung are agglutinated, and sometimes a sac of pus is pent up between them, forming a variety of encysted pleurisy. Such an abscess may break into a bronchus. It is not usually recognized before autopsy.

Diagnosis.—The certain diagnosis of pleurisy depends almost entirely upon the physical signs, for, however severe the other symptoms, there is nothing in them by which the disease can be surely recognized. In the majority of cases of pleurisy the diagnosis is made easy by the aid of these signs. It is true there is a certain resemblance between pleurisy and *pneumonia* in the first stage of each, and in that stage a diagnosis is often difficult, especially when the physical signs are not distinct. The resemblance of the

friction sound to the crepitant r le is well recognized. The usual distinctive features are the superficial situation and the intermittent character of the friction sound, its presence during expiration as well as inspiration, and if confined to one of these acts, rather to expiration, while the crepitant r le is heard only during inspiration. The friction sound is also usually rougher and more circumscribed, while it may sometimes be heard better with the stethoscope. Pain is very apt to be elicited in pleurisy if the stethoscope is pressed hard upon the chest. As the pleurisy becomes dry and adhesions form, the friction sound resembles more closely that of creaking leather.

In the second stage of pleurisy, too, furnishing as it does a dullness on percussion like that of the same stage of pneumonia, and frequently bronchial breathing, we have also a resemblance in the physical signs. But it is true of the bronchial breathing of pleurisy that it is commonly best heard at the upper border of the dullness and least where the dullness is most marked; whereas, in pneumonia the bronchial breathing is most intense where the consolidation is greatest. *Above all, in pleurisy with effusion there are diminished vocal fremitus and diminished vocal resonance; in pneumonia, increased vocal fremitus and increased vocal resonance.* There is commonly, further, in pleurisy with effusion, a change of level of the dullness with a change of the position of the patient, which is not the case in pneumonia. The egophonic voice is also often here present in pleurisy; whereas we have only bronchophony in pneumonia. Finally, in the differential diagnosis between acute pleurisy and pneumonia, the trifling cough and absence of expectoration in the former are valuable signs, though it must not be forgotten that in old persons there is sometimes very little cough in pneumonia.

As to further differential diagnosis, pleurisy in the dry stage has been mistaken for *muscular rheumatism, intercostal neuralgia, periostitis, and caries of the ribs*, and even *gastralgia and ulcer of the stomach*. The absence of fever in the first two, the circumscribed situation of disease of the ribs, and the associated history of *gastralgia and ulcer of the stomach*, serve to differentiate them.

The confusion of *mediastinal tumors* arising from the pleura itself with pleurisy is a natural error, especially since such tumors in their turn produce pleurisy. In pleurisy, the physical signs are commonly limited to one side, while in mediastinal tumor the fremitus is less diminished, the dullness extends upward, is more irregular, and more circumscribed; while symptoms of compression of nerves and vessels, and of encroachment on the esophagus sooner or later make their appearance. Repeated exploratory punctures may be necessary to settle the diagnosis, which, after all, may require some time.

The impulse of a *pulsating empyema* sometimes very strongly suggests an aneurysm, but the empyema furnishes no murmurs or pressure symptoms, while the location is usually different from that of aneurysm.

Prognosis.—The prognosis of acute pleurisy depends largely upon its cause. The simple pleurisies which are the result of cold always get well, and recovery is the termination in most cases even when there is large effusion, if the exudate remains serous. It has already been said that a purulent pleurisy is, in the vast majority of instances, tubercular. We have learned, however, that a tubercular pleurisy is not necessarily fatal, and it is more than likely that some of the cases of healed empyema with which we are familiar are instances of such recovery. Others are cured by the introduction of drainage-tubes and exsection of ribs, but often the patient slowly

succumbs to the exhausting effect of the illness or to tuberculosis of the lungs. Not a very rare event is the spontaneous rupture of such a pleurisy outward, an event better anticipated by paracentesis. Very stubborn, too, are the somewhat rarer cases in which perforation takes place from the pleural sac into the lungs, adding the symptoms of a pneumothorax to those of the pleurisy. Yet even these sometimes heal spontaneously.

Though not a frequent event, sudden death, when least expected, is sufficiently so to make it important that one should be on his guard for it. It is not alone when the chest is full, or during a tapping, that it occurs, but it may happen several days after a large part of an effusion has been removed. Pulmonary thrombosis is probably the most frequent cause. A case of my own terminated thus, when convalescence was thought to be established, and the patient expressed himself better than on any day during his illness. At the necropsy, a white "chicken-fat" clot was found in the right ventricle, extending as a red clot into the pulmonary artery. The chest was partly filled with serofibrinous fluid. Edema of the opposite lung and degeneration of the heart muscle are probable causes, suggested by Weil. Obstruction to the circulation by dislocation of the heart or twisting of the great vessels has also been suggested as a cause.

Treatment.—Many simple pleurisies doubtless get well of themselves, with, perhaps, more or less adhesion of the lung, which may be the cause of certain unexplained restrictions in expanding the chest. For very severe cases of pleurisy, local blood-letting is the promptest measure of relief, and there is no condition in which so delightful an effect comes to the suffering patient gasping for breath and racked with pain. I am confident, too, that the duration of many pleurisies would be shortened by such a treatment. In its absence, the next best measure is the application of a blister, which seems to suspend the process, as well also as to relieve the pain in the less severe cases. Succeeding the blister, a cotton jacket or a poultice should be applied, for a time at least. Anodynes—morphin hypodermically is the best—are often necessary to relieve the pain, and must sometimes be repeated, while I have even known repetition to be inefficient and unsatisfactory, when a blood-letting produced prompt relief.

Even where the effusion is considerable, it often passes away without any very active measures. The blister aids in its absorption, however, and the iodid of potassium may be used in co-operation—five to ten grains (0.32 to 0.65 gm.) every six hours. If there is much delay, however, in the absorption of fluid, *paracentesis thoracis* should be practiced as soon as the fever has subsided. It is an operation every physician should be ready to do without calling on the surgeon. I prefer for it the line of the angle of the scapula between the eighth and ninth ribs, and, while it is true that the chest-wall is a little thicker here, and sometimes perforation is not immediately easy, it is a point freer from danger to adjacent organs than the side where the chest-walls are really thinner. The point for tapping preferred by others is the seventh interspace in the midaxillary line. The interspaces are made wider and the operation easier if the arm of the side to be operated is carried over to grasp the opposite shoulder. The needle should be introduced close to the upper margin of the rib, so as to avoid wounding the intercostal artery. Local anesthesia should be obtained by the application of ice and salt, or by chlorid of ethyl. It is particularly in the insidious forms of pleurisy that the tapping of the chest becomes necessary, because they seem to be as slow to disappear as they are slow to make their presence

known. A further indication for paracentesis is aggravated dyspnea. The operation is usually well borne, though sometimes faintness results. It is, therefore, well to fortify the patient in advance with an ounce of whisky, and if faintness results, to desist. Sudden death during the operation has happened in rare instances. On the other hand, sudden death has occurred more frequently in cases of full pleura without operation. When this accident occurs, it is more than likely that the heart was previously damaged.

Empyemas almost never get well after a simple tapping. The pus reaccumulates, and the symptoms and physical signs are renewed. Free opening should be made without delay, and a good large drainage-tube passed into the chest through an upper and out through a lower opening in the chest-wall. The drainage-tube is often very much too small. In the event of failure of the drainage-tube to effect a cure, which at best requires weeks, with daily washing out of the chest cavity, exsection of a part of one or two ribs is sometimes practiced with better results. A cure means thorough union of the pulmonary and costal pleuræ, and complete obliteration of the pleural sac.

CHRONIC PLEURISY.

Definition and Pathogeny.—Under the term chronic pleurisy are included several morbid states, the result of inflammatory processes of longer duration than a few weeks. These include both *exudative* and *dry* or *plastic* pleurisies.

1. *Exudative pleurisies*, characterized by liquid product, include—

(a) The condition already spoken of as *latent pleurisy* associated with effusion.

(b) *Suppurative pleurisies*, all of which, though they may originate acutely, are always of long duration, and may therefore be appropriately classified as chronic.

2. *Plastic pleurisies*, characterized by a dry product. These originate in two ways: First, they are plastic from the beginning—that is, the so-called lymph first deposited becomes permanently organized as a more or less thick layer uniting the pleural surfaces. Such primary adhesions are more usual in circumscribed areas of pleural surface. Second, the same result follows when the surfaces separated by the more copious sero-purulent transudate reapproach each other as the latter is absorbed, producing secondary adhesions. Third, we have a most distinctive product of chronic pleurisy in the cicatricial tissue, which succeeds the healing of the extensive suppurative surfaces forming the walls of an empyema and which also closely cements the lung to the costal pleura.

Mention should also be made of the form of chronic pleurisy resulting in a thick interpleural deposit of slow formation, also tubercular in origin, which extends its new formation from the pleura into the interlobular tissue of the lung, dividing it or dissecting it in extreme cases into distinct areas, well shown upon section, which has given rise to the name *pneumonia dissecans*, or pleurogenous pneumonia. This form of pneumonia has its type in the pleuropneumonia of cattle. I have met one striking instance of this form of chronic pleurisy of tubercular origin in man. Any one of these varieties of chronic pleurisy may originate as a tubercular pleurisy, and probably most of them are of this kind.

The morbid product of chronic pleurisy requires no further description than has just been given, and in the description of the morbid anatomy of acute pleurisy, which necessarily included to some extent that of its frequent termination in the chronic form. The adhesion between the lungs and the ribs is variously close and the product variously thick, insomuch that while usually the two surfaces are easily dragged apart, sometimes it is impossible to do this without lacerating the lung. Attention may again, however, be called to the displacement of viscera, the retraction of the chest-wall, and curvature of the spinal column, which sometimes take place as a consequence of the extreme contraction of the plastic product of chronic pleurisy in its most aggravated form—that with empyema.

Treatment.—It need only be added to what has already been said in the treatment of acute pleurisy that, in chronic pleurisy especially, chest gymnastics, consisting in systematic inspiratory efforts and massage of the thoracic walls, must be availed of. Operative procedures must be considered in conjunction with the surgeon. Mild local measures, such as counter-irritation by iodine and counter-irritating ointments, may be useful to relieve pain, which sometimes annoys the subjects of chronic pleurisy. Nothing more can be accomplished by active counter-irritation by blisters.

HYDROTHORAX AND HEMATOTHORAX.

Definition.—The term hydrothorax is applied to any accumulation of clear serum in the pleural sacs.

Etiology.—It is the result mainly of resistance to the free circulation of the blood through the vascular basis of the pleural membrane. It occurs as a part of general dropsy, however caused, but Bright's disease or valvular heart disease are the most frequent causes. Hence the chest should be frequently examined in these diseases, as hydrothorax may be the first symptom of dropsy. Hydrothorax is usually bilateral in both renal and heart affections. In a careful study of this subject by J. Dutton Steele,* based upon a large number of autopsies with cardiac hydrothorax, in about 83 per cent. of cases the effusion was bilateral, and in 17 per cent. unilateral. Of the bilateral, 70 per cent. were unequal in distribution, and of these, three-fourths were greater on the right side. Of the 13 unilateral cases, 10 were right-sided and 3 left-sided. The usual explanation of this preference of pleural effusion to the right side in cardiac hydrothorax is that more frequently pressure is exerted by a dilated right auricle upon the root of the right lung, interfering with the return circulation from the pleural sacs. Left unilateral effusion occurs as the result of pressure upon the root of the left lung and left superior intercostal vein. Unequal bilateral pleural effusions must, therefore, be due to unequal pressure on the roots of the two lungs. The serous fluid in hydrothorax is characterized by the small amount of albumin as compared with that exuded in pleurisy.

Symptoms.—The symptoms are those of pleuritic effusion, both as to subjective symptoms and physical signs. Crepitant râles are sometimes heard in the lung above the effusion, due to its retraction and to partial atelectasis.

Treatment.—This is considered under that of the diseases causing the hydrothorax.

* "Distribution and Etiology of Cardiac Hydrothorax," "University Medical Magazine," vol. ix., 1897, p. 563.

Hematothorax is a term applied to any accumulation of blood in the thorax, however caused. It may be due to the wounding of vessels, malignant disease, or aneurysmal rupture. The symptoms and physical signs and treatment are those of pleural effusion.

PNEUMOTHORAX.

SYNONYMS.—*Hydropneumothorax*; *Pyopneumothorax*.

Definition.—Pneumothorax means air in the thorax, but the term is limited to the condition in which there is air in a pleural sac. It is almost always accompanied by a liquid inflammatory exudate, usually purulent or seropurulent, whence the terms *pyopneumothorax* and *seropneumothorax*. The effects of pneumothorax are compression of the lung, almost always dislocation of the heart toward the opposite side, and in some instances displacement of the liver and spleen. Pneumothorax is almost without exception one-sided, though it is not impossible for it to be double.

Etiology.—The most frequent cause is perforation of the pleura over a phthisical cavity or a hemorrhagic infarct, or over a septic bronchopneumonic focus, or gangrene of the lung. Other causes are perforating wounds of the lung, perforation of the diaphragm due to malignant disease in the abdomen, especially cancer of the stomach or colon, or of the esophagus. Perforation into the lung from the pleural side may occur in empyema. Rupture of the lung due to straining has caused it. The opening may be valvular, so as to admit air intermittently.

Symptoms.—*Sudden pain* and *increased dyspnea* usually usher in a perforation causing pneumothorax, though the effect may be more gradual. Sometimes the symptoms are more severe, constituting those of *collapse—faintness, frequent pulse, and lowered temperature*. Later, at least slight fever, corresponding acceleration of pulse and breathing rate, continue while the condition lasts. Pneumothoraces have also been found postmortem when unsuspected before death, having occurred without producing symptoms. The patient may be orthopneic, or may lie upon the affected side, for the same reason as in pleurisy. Pleurisy is a frequent, but not invariable, consequence, and superadds its own symptoms, most palpably effusion.

Physical Signs.—These are the most distinctive symptoms. Inspection recognizes commonly a bulging half-chest, with the intercostal spaces obliterated or prominent, as compared with the opposite side. The breathing is frequent and short. Palpation recognizes absent or very indistinct vocal fremitus, the lungs being no longer in contact with the chest-wall, which is also in a state of tension interfering with vibration. The percussion note is resonant, often ringing and amphoric over the upper part of the side,—that containing air,—while over the area below, containing the fluid, there is absolute dullness. On the other hand, there may be dullness over the air-containing space, instead of tympany, on account of the extreme high tension checking all vibration. We may also meet here that interesting modification of tympany known as Biemer's change of note, based upon the fact that with a given tension the larger an air-containing cavity, the lower the pitch of the percussion note. If the patient with *pyopneumothorax* sits, or especially stands, in the upright position, the pleural air-containing space is enlarged, because the weight of the fluid pushes the dia-

phragm downward, whereas in the horizontal position the fluid flows into the gutter between the ribs and spinal column, the diaphragm rises, the cavity becomes smaller, and the pitch of the percussion note is raised. There is also the usual change of level of the dullness corresponding with change of position, as in pleurisy with effusion.

Auscultation recognizes feeble or absent vesicular murmur in the situations where it is present in health, while amphoric breathing may be substituted—bronchial breathing of a metallic character. Ringing amphoric bronchophony is also heard when the patient speaks. An interesting auscultation sign is the so-called “metallic tinkling,” a sound ascribed to the dropping of liquid from the seat of perforation into the fluid below. Here also is produced in its typical expression the “coin-clinking” sound conveyed to the ear of the auscultator listening at the back of the chest, while a coin placed against the chest in front is tapped by another coin. This is a sign usually limited to pneumothorax, though it may also be produced over bronchiectatic cavities. Here, too, may be produced the well-known Hippocratic succussion sound by shaking the body of the patient, the splashing being intensified in the air-distended cavity.

Diagnosis.—Almost the only condition with which pneumothorax may be confounded is *diaphragmatic hernia*, the physical signs of which very closely resemble those of pneumothorax. The causes of diaphragmatic hernia are usually severe traumatic agencies, such as compression between cars or under masses of earth, yet occasionally more trifling causes produce it, as in the case referred to on page 535. If such a condition be suspected, all doubt may be settled by passing a stomach-tube or sound, which will disclose the exact position of the viscera. A *distended stomach* itself is named as a source of confusion with pneumothorax, and it is true that succussion and metallic tinkling can be elicited in it in great perfection. The absence of distention of the thorax itself, the limitation of the physical signs to the neighborhood of the stomach, their association with movements of the stomach quite independently of breathing, point to the proper source. Pneumothorax is scarcely likely to be confounded with large *tubercular cavities*, for while the latter furnish amphoric signs over them, vocal fremitus is increased, or at least remains distinct, while with pneumothorax vocal fremitus is diminished or absent. Further, there is at least no prominence over cavities, while there is often depression, and succussion signs cannot be elicited. Finally, cavities are circumscribed. *Bronchiectatic cavities* furnish signs behind and below the scapula, and therefore more in the situation of those of pneumothorax, but there is dullness instead of tympany, no bulging, and vocal fremitus probably remains distinct, while there is often pectoriloquy, never present in pneumothorax.

Treatment.—This is mainly symptomatic. Sudden pain and extreme dyspnea must be treated by morphin, preferably subcutaneously; embarrassing accumulation of fluid by thoracentesis and draining of the sac, and in extreme cases the air may be liberated in a similar manner. Often pneumothorax gives surprisingly little inconvenience, and it is by no means impossible for spontaneous healing to take place. Potain suggested replacing the air and fluid by sterilized air, but such air would soon be substituted by impure air. Operative interference has been carried out with more or less success.*

* See a paper on the “Operative Treatment of Pneumothorax,” by Samuel West, “British Medical Journal,” November 27, 1897, p. 568.

MORBID GROWTHS OF THE PLEURA.

These are rare and will be considered to some extent in treating mediastinal disease. The pleura is subject to *carcinoma* and to *sarcoma*, the clinical phenomena of which are identical. Most cases of carcinoma of the pleura arise by contiguous growth from primary cancer of the lung. Secondary cancer of the pleura occasionally arises by metastasis from the mammary gland or lungs.

Sarcoma occurs as a primary growth in the shape of the so-called endothelial carcinoma of Wagner, which starts from the endothelial cells of the lymphatics and connective tissue. It also gives rise to secondary deposits in the lungs, lymphatic glands, the liver, and muscles.

The **symptoms** of any one of these forms of growth are those of chronic pleurisy, varying in intensity with the extent of the growth, single secondary nodules often giving rise to no symptoms, while the diffuse forms, spreading from the lungs, cause all the symptoms described as belonging to chronic pleurisy, the lung symptoms being relatively insignificant. In the meantime the true nature of the disease may long remain unknown, its real nature being determined with the development of cachexia toward the end, the decline of strength, and probably secondary deposits in discoverable localities. The bloody character of the effusion is a sign pointing to malignant disease of the sarcomatous or carcinomatous type.

The **prognosis** is altogether unfavorable, and **treatment** is palliative only.

There are also sometimes found in connection with the pleura *chondroma* and *lipoma*, while *calcification* sometimes takes place in chronic inflammatory products.

Echinococcus or *hydatid disease* is occasionally found in the pleural cavity. Of this, the first clinical symptom is hydrothorax, the fluid from which is non-albuminous, differing in this respect from that of pleurisy and to a less degree from that of ordinary hydrothorax. The only unmistakable evidence of hydatid disease is the presence of hooklets and fragments of the hydatid cysts in the aspirated fluid. Here, also, the product may be purulent.

MEDIASTINAL DISEASE.

Definition.—Under mediastinal disease are included all anatomically morbid conditions situated in the mediastinal space, except diseases of the heart, aorta, trachea, and esophagus. By far the greater number of these are tumors, but simple lymphadenitis, abscess, and hemorrhage are also included.

Anatomical.—In consequence of the difficulty attending the conception of the mediastinum and its contents, I precede the consideration of mediastinal disease by a brief anatomical description of the mediastinum and its spaces.

The mediastinum is bounded in front by the sternum, posteriorly by the vertebral column from the lower edge of the fourth dorsal vertebra downward, and laterally by the two pleuræ. Clinicians are in the habit of subdividing this space into the *anterior*, *middle*, and *posterior* mediastinum or

mediastinal spaces. The portion above this is called by anatomists (notably Struthers and Gray), whom I follow, the upper or *superior mediastinum*.

The *superior mediastinum* is that portion of the interpleural space above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebrae behind, and bounded below by a plane passing

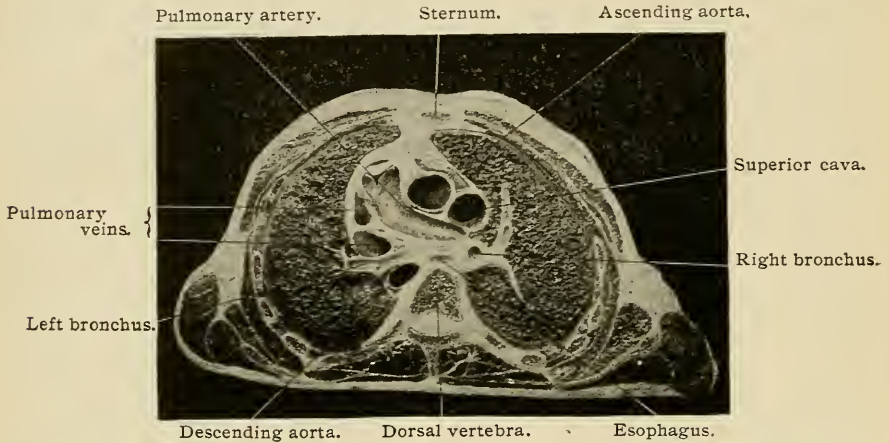

Fig. 49.—Section through Frozen Thorax at Second Interspace in Front, Looking from above downward, Showing Mediastinal Spaces.

from the junction of the manubrium with the body of the sternum backward to the lower border of the fourth dorsal vertebra. It contains the origins of the sternohyoid and sternothyroid muscles, and the lower end of the longus colli; the transverse portion of the arch of the aorta; the innominate, the left

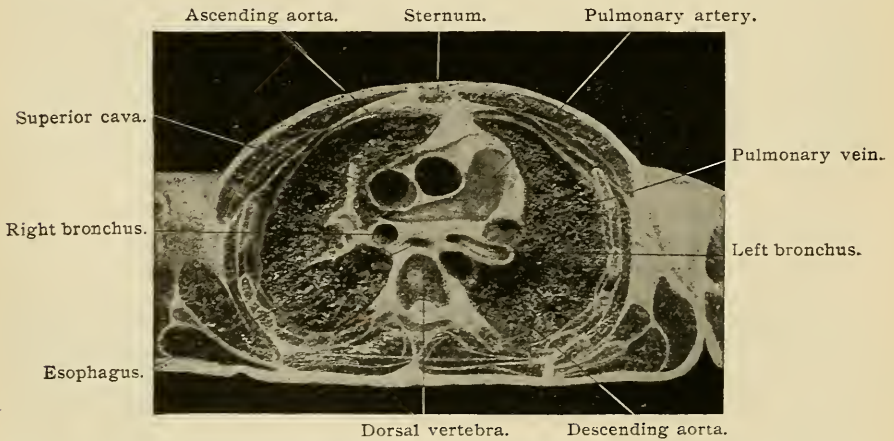

Fig. 50.—Section through Frozen Thorax at Second Interspace in Front, Looking from below upward, Showing Mediastinal Spaces.

carotid, and left subclavian arteries; the superior vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, esophagus, and thoracic duct, and the remains of the thymus gland with lymphatics.

The *anterior space* of the lower or clinical mediastinum is bounded in

front by the sternum, posteriorly by the pericardium, and laterally by the pleuræ. It is wider below than above, and is narrowest in the middle, since at this point the two pleural edges approach each other, while in some instances they are actually in contact. The anterior mediastinum contains the origins of the triangularis sterni muscles; the internal mammary vessels of the left side; a quantity of loose areolar tissue; a few lymphatic glands, with lymphatics from the upper surface of the liver and two or three lymphatic glands called anterior mediastinal glands.

The *middle space* contains the heart in its pericardial sac, the ascending aorta, the superior vena cava, the pulmonary artery and veins, the phrenic nerves, the bifurcation of the trachea, and the roots of the lungs, with numerous lymphatic glands. It is broader than the anterior or posterior mediastinal space.

The *posterior space* is triangular in form, and is bounded behind by the vertebral column. Its anterior boundary is the pericardial sac and the roots of the lungs; its lateral walls, the pleuræ. It contains the descending portion of the arch and the descending thoracic aorta; the greater and less azygos veins, the thoracic duct, the pneumogastric and splanchnic nerves, the esophagus, and some lymphatics.

MEDIASTINAL TUMORS.

Historical.—The celebrated English physician and acute observer, Thomas Willis (1621-75), seems to have been the first to have made an observation on mediastinal disease. H. Boerhaave recorded a steatoma of the anterior mediastinum in 1742. Joseph Lieutaud (1703-80) described several cases. Boole published others in 1812, and J. G. C. F. M. Lobstein gave the first text-book description in 1835, after which cases multiplied, although the number which came under the notice of any single observer was always few. F. Strausched analyzed 112 cases in 1887, and Hobart A. Hare collected 520 cases in his Fothergillian Essay in 1889. Out of 7566 autopsies at the Marine Hospital at Cronstadt, 158 subjects were found to have tumors of the mediastinum said to be malignant. A study of mediastinal disease by the late William Pepper and Alfred Stengel, published in the Transactions of the Association of American Physicians in 1895, is noteworthy.

Pathology and Morbid Anatomy.—The varieties of growth consist mainly of sarcoma, including lymphosarcoma, carcinoma, simple lymphadenoid tumors; more rarely cysts, dermoid and hydatid, fibroma, lipoma, gumma, and chondroma; also the teratoma myomatoids of Virchow. Sarcoma and carcinoma and lymphadenoid tumors make up the larger number. Most observers have found more carcinomata than sarcomata, but in the light of the fact that many tumors formerly described as cancerous are at the present day acknowledged to be sarcomata, it is more than likely that the latter have always predominated. Hilton Fagge and Douglas Powell were the first to announce this, and William Pepper and Alfred Stengel, in their monograph published in 1895, came to the same conclusion.

The majority of tumors in the anterior mediastinum start from the remnant of the thymus gland and are lymphosarcomata. The lymphatic structures in the anterior mediastinum furnish a few. In the middle mediastinum the lymphatic glands are the principal starting-points of the relatively frequent lymphosarcomata. The carcinomata are usually primary, but secondary carcinoma is not infrequent. The breasts, lungs, and stomach are among the primary seats named. The secondary cancers do not usually attain a large size. Cancer may extend from the abdomen to the lymphatic glands of the chest by vascular embolism, by direct spread of the disease to

the under surface of the diaphragm, through which it may penetrate along the lymphatics into the chest and glands, or by embolism through the thoracic duct to the chest and then by retrograde embolism to the mediastinal glands.

The pleura is also a frequent starting-point of mediastinal growths. Among these are the so-called endotheliomata of Wagner and Schulz, starting in the endothelium of lymphatic vessels and sometimes the surface endothelium. They are sarcomata or carcinomata according as the endothelium is counted mesoblastic or endodermic in origin. The cases of primary cancer of the pleura are probably endothelioma. Fibrous, fatty, and calcareous tumors of the pleura are of rare occurrence. The lungs also contribute tumors to this locality—carcinoma, primary and secondary, and sarcoma, primary and secondary. Of the primary tumors, carcinoma is the more common, but primary sarcoma of the lymphatic glands surrounding the bronchi and within the lungs near the root is not very rare. The clinical symptoms are the same as when the glands around the bronchi outside of the mediastinum are affected. The cancers may start from the surface epithelium of the bronchi, from the mucous glands, or from the alveolar epithelium of the lung. Finally, from the esophagus, also, start cancerous tumors invading the mediastinum, usually small, though not always. From these the posterior mediastinum and lungs may also be invaded.

Symptoms.—Mediastinal tumors may be *latent*. Their symptoms when present are, in a word, those of *pressure*. Such pressure may involve the lungs, the trachea, the bronchi, the esophagus, the heart, the vessels, and the nerves of this locality. They include symptoms, subjective and objective, of the usual kind, and also physical signs. It will be remembered that the symptoms of aneurysm are also largely those of pressure, and it is chiefly from aneurysm that mediastinal tumor is to be distinguished, often a matter of some difficulty. The division by Pepper and Stengel into three groups affords the most convenient mode of studying these symptoms. These groups are:

1. Those in which the anterior mediastinum is the seat of the growth.
2. Those involving the middle and posterior spaces.
3. Those in which the pleura or superficial portion of the lung is involved.

1. *Intrathoracic Tumors Situated in the Anterior Mediastinum.*—The symptoms are mainly those arising from pressure exerted on the venous trunks, the superior vena cava, and the right and left innominate veins. The yielding walls of these vessels as contrasted with the firmer adjacent arteries easily suffer compression, and may even be penetrated by the growths which may proliferate within them, sometimes causing occlusion by thrombosis. The consequence is *distention* of the *veins* of the *upper part of the body*—the head, neck, and upper chest, sometimes the arms. Coldness, lividity, edema, and clubbing of the ends of the fingers result, while the superficial venous channels may be dilated and tortuous. From pressure on the arteries may result *inequality* of the *radial pulses*. Of the nerves, the inferior laryngeal is especially liable to compression, with resulting *hoarseness* and *aphonia*. The sympathetic is also sometimes compressed, with consequent *inequality of pupils*, the pneumogastric being less frequently involved than when the tumor occupies a more posterior situation. As the tumor enlarges and the air-passages are intruded upon, dyspnea makes its appearance. *Dyspnea* is usually of the inspiratory kind. *Pericarditis* and *pleurisy*, with pain, hydro-pericardium, and pleural effusion may be present. With the prolongation of the disease the patient wastes, but it is said that *cachexia* is less apt to

develop than in malignant growths of the posterior mediastinum. *Pain* is not always present—indeed, it is said to be *less marked* than in aneurysm.

Physical Signs of Growths in the Anterior Mediastinum.—To *inspection* the sternum is frequently pushed forward, and in a few instances eroded. Vocal fremitus may be either increased or diminished. Percussion elicits abnormal dullness, characterized by more or less irregular shape. Pulsation may occur, but is rare, while the sharp diastolic shock of aneurysm is wanting. If the tumor extends upward sufficiently, it may be felt in the supra-sternal fossa. *Auscultation* over the area of dullness may be negative, but sometimes the breath-sounds and heart-sounds are well transmitted, while a distinct systolic bruit may be produced by pressure on the aorta or the pulmonary artery. Secondary enlargement in the cervical lymphatic glands sometimes makes its appearance.

2. *Intrathoracic Tumors in the Middle and Posterior Portions of the Spaces around the Bronchi, Esophagus, Aorta, and Nerves*, and in which the symptoms predominate over the physical signs.—The first effect is likely to be pressure on the trachea and bronchi. Hence dyspnea is an important and early symptom of tumors in this situation, and the inspiratory effort is extreme. Pressure here is also exerted upon the vena cava ascendens, whence results edema of the *abdominal walls and lower extremities*. The effect of pressure on the arteries is not serious. From pressure on the vagus nerve arises *peculiar cough*, paroxysmal and whooping. Sometimes it is loud and ringing, at other times constant and hacking. This is said to be due to the joint involvement of one vagus and the pulmonary plexus; whereas experimentally two pneumogastrics are required to be cut to produce this symptom. The explanation is in the involvement of the pulmonary plexus. Mucopurulent and even *blood-stained sputa* may attend the cough. The latter is sometimes a sign of perforation of the bronchial wall. *Dysphagia* from pressure on the esophagus is a symptom in this group, sometimes, indeed, the only one. It is not, however, invariably present. Vomiting, cardiac palpitation, with irregularity, and syncope, when present, are also ascribed to the pneumogastric involvement. *Pressure upon the azygos veins* may cause edema of the upper part of the abdomen and serous effusion in the chest, while pleural effusions are also due to complicating inflammations or neoplasms of the pleura. *Fever* may be a symptom of tumor of the posterior mediastinum. It is usually moderate, but is sometimes high and irregular, followed by sweating. On the other hand, there may be lowered temperature, as in tumor of the anterior mediastinum from impeded circulation.

Cachexia is much more frequent in this group of symptoms, as might be expected from the greater severity and disturbing effect of the disease, including, as it does, destructive process involving bone and lung structure, as well as severe and deep-seated pain.

Physical Signs.—It is evident that in this group the physical signs play a secondary rôle, and except as the result of modified breathing by pressure and impairment of resonance to percussion, have little significance.

3. *Tumors Originating in the Pleura and Lung*, and in which the symptoms and physical signs are of equal prominence. The former is the more frequent starting-point, but the underlying lung is usually soon invaded and may be more frequently the actual starting-point than is commonly supposed. Naturally, the *symptoms first produced are those of pleurisy*, and the disease is generally so regarded at first, being characterized by the com-

paratively sudden onset, sharp pain, cough, embarrassed breathing, and pleuritic effusion. Instead of abating ultimately, as is the course in pleurisy, these symptoms grow worse, especially the pain, which extends along the intercostal nerves and their distribution and to the neck and arms. The cough also persists, while the expectoration may become bloody and include sometimes cells from the morbid growth.

Paracentesis, too, is successful, and often furnishes in the peculiarity of its product valuable aid in the diagnosis, because, instead of being clear or nearly so, it is apt to be bloody or slightly chyliform from the presence of fatty matter. This fatty character has been found where there were cancer and sarcoma. The diagnostic importance of certain large, swollen cells of endothelial nature, which seem to become detached and transformed only in case of pleuritic disease of malignant character, is insisted upon by Fraenkel. To the information gained from the fluid obtained by tapping are added also unusual resistance to the trocar and imperfect relief to the dyspnea. Rapid emaciation, anemia, and cachexia complete the picture, while all doubt is removed if secondary growths make their appearance in the lungs, as not infrequently happens.

Diagnosis.—In view of the similarity of symptoms to *aneurysm*, the history of the case in mediastinal disease becomes of the utmost importance, but shortness of breath, the bulging of the thorax, irregular outline of percussion dullness, the feebleness of breathing sounds, the dislocation of the heart and sometimes of the abdominal organs, the symptoms of venous engorgement, which are usually more marked in mediastinal disease, the more rapid course, and secondary metastatic deposits are strong points in favor of the latter as contrasted with aneurysm. Laryngoscopic examination with a view to discovering any constriction of the trachea from pressure by the tumor may be availed of. The subjects of mediastinal disease are usually younger than those of aneurysm. Bony erosion and pain are less frequent. Constitutional disturbance and emaciation are more marked. Diastolic shock is never present in mediastinal disease, while pulsation, if present, is not expansile.

Confusion with *pleurisy* and *pericarditis* is a natural error when the symptoms involving the pleura and pericardium are recalled, and here the slower development of the symptoms associated with those of compression of the various mediastinal tissues and absence of tendency to improve should lead to suspicion of the true nature of the disease.

The nature of the tumor may even be suspected from certain features. Thus, rapid growth, metastatic deposits in the glands of the neck and apices of the lungs, cachexia, and tumors in other situations point to malignancy. Especially may sarcoma be suspected if the subject be a youthful one. Abscess may be suspected if there is a history of injury, caries, or pyemia, or if there is abscess of the lung or empyema attended by the supervention of pressure symptoms. Hemorrhage may be suspected also when there is trauma and the symptoms develop very rapidly.

Treatment.—There is no treatment for mediastinal disease, except such as may suggest itself for the palliation of symptoms.

Mediastinal Abscess.—Separate mention should be made of mediastinal abscess, since it is relatively not a very rare disease. Out of Hare's 520 cases of disease of the mediastinum 115 were abscesses, as contrasted with 134 cases of cancer and 98 of sarcoma, 21 cases of lymphoma, 7 of fibroma,

11 of dermoid cyst, 8 of hydatid cyst, with isolated cases of gumma, chondroma, and lipoma.

The abscesses were found in the majority of instances in males, most often in the anterior mediastinum, and most could be traced to traumatic causes. Other causes were tuberculosis, the eruptive fevers, and erysipelas. A few cases of mediastinal abscess also originate in the bronchial and tracheal lymphatic glands, as tubercular lymphadenitis. In fifty-four cases the abscess was acute.

Of **symptoms**, *substernal pain*, sometimes throbbing, was the most conspicuous. To this was added *fever* in acute cases; sometimes *chills* and *sweats*. Erosion of the sternum and burrowing along a rib into the abdomen were noted, also rupture into the trachea and esophagus. In chronic abscess the pus may become inspissated—cheesy. Suppurative lymphadenitis has been known to terminate thus, previous symptoms having been masked by the lung affection. Rarely are we able to detect fluctuation at the edge of the sternum and in the suprasternal notch, where there may be pulsation. Only as the abscess becomes large enough to encroach upon the air-passages does it cause dyspnea.

The *physical signs* are not distinctive. They are essentially those described in the general description of mediastinal disease. Fever, throbbing pain, fluctuation, and the history of trauma are symptoms which, if added, aid the diagnosis.

As to **treatment**, given a correct diagnosis, operative interference is justified, and likely to afford relief if the pus is reached.

Simple Lymphadenitis.—This probably occurs to a degree, in all inflammatory affections of the bronchi and of the lungs, but is rarely recognizable. The glands are mostly in the posterior mediastinum, and their enlargement may be appreciable to percussion in the upper interscapular region behind, though lymphatic enlargement may contribute also to dullness in the region of the manubrium. Tuberculosis may affect these glands.

SECTION IV.

DISEASES OF THE HEART AND BLOOD-VESSELS.

GENERAL SYMPTOMATOLOGY OF CARDIAC DISEASE.

1. **Shortness of Breath, Cardiac Asthma.**—Shortness of breath is commonly the first symptom of cardiac disease. At first it is very slight, being felt only on exertion. As the disease advances it is induced by slighter effort, and finally it is more or less permanent. The higher degrees are commonly characterized as cardiac asthma. It differs essentially from bronchial or spasmodic asthma:

1. In that there is no spasmodic contraction of the bronchial tubes.

2. In that the essential morbid change is an overfilling of the pulmonary capillaries which, intruding on the lumen of the air vesicles, interferes with the access of air to the blood, causing an *ἄσθμα*, or panting, an effort by frequent and deep breathing to accomplish aëration. The overfilling of the pulmonary capillaries is commonly caused by a backing of blood from the left heart into the lungs, because of valvular insufficiency, or it may be caused by a weak right heart.

The same results follow in the so-called *paretic* cardiac asthma due to dilatation of the left ventricle. This is a common condition of the senile heart in consequence of its imperfect nourishment, and is especially prone to occur when a feeble heart is forced to overcome an unusual resistance. Such is the increased arterial tension due to arteriosclerosis and chronically contracted kidney, both of which are often associated with shortness of breath. In both the blood does not pass from the arteries into the veins so freely as it ought. So long as the heart is well nourished it hypertrophies in these diseases and overcomes the resistance, but as soon as its nutrition fails, it slowly undergoes dilatation, the blood is backed into the lungs, and the asthma occurs.

In cardiac asthma as contrasted with bronchial asthma there is an absence of the wheezing râles which characterize the latter and obscure the vesicular element of the breathing sound, at first unaltered in cardiac asthma. Later, if edema of the lungs occur, there may be small, moist râles, crepitant or subcrepitant, and still later, if the air vesicles fill up, bronchial breathing with an impairment of resonance. In bronchial asthma if there happen to be, as indeed there often is, associated emphysema, there is hyperresonance. Under these circumstances the normal areas of cardiac and hepatic dullness are diminished. Bronchial asthma is an asthma of expiration, as spasm of the larynx furnishes an asthma of inspiration. In the former the lungs are overdistended and the difficulty lies in getting them emptied. Hence expiration is four or five times longer than inspiration. Yet it is ineffectual. In cardiac asthma there is no obstruction to inspiration or expiration and both share in the overeffort to accomplish the perfect aëration of the blood. The air vesicles do not receive enough air to aërate the blood because the latter is in excess. Cardiac asthma and bronchial asthma are sometimes associated.

2. **Palpitation.**—The second symptom characteristic of heart disease

and next in order of frequency after shortness of breath is palpitation. By palpitation is meant undue frequency of the heart's action, with or without irregularity. It succeeds very early upon shortness of breath, or is coincident with it, and is more common in mitral disease than in aortic disease. It varies greatly in degree, being at times scarcely noticeable by the patient, and at others exceedingly distressing. The rate attained by the heart under these circumstances is sometimes as great as 200 in a minute, more frequently 120 to 150.

3. Slow-pulse.—Unnaturally slow action of the heart as a symptom of organic heart disease is not infrequent. The number of heart-beats is reduced to forty, twenty, or even less. It is more frequently associated with muscular disease of the heart and disease of the coronary arteries, and is distinct from nervous bradycardia, to be separately considered. The immediate cause, as in the case of palpitation, is deranged innervation of the heart, the inhibitory nerves, with their ganglia situated in the heart muscle, being the usual medium by which it is brought about.

4. Pain.—Pain is not so frequent in heart disease as is palpitation or dyspnea. It is of two kinds—a dull, aching pain and a sharp pain of great severity, radiating through the heart and down the arms, especially the left arm. Sometimes the patient complains of a sensation as if the heart was being compressed, or even as if grasped in a vise. The pain is associated with an anxious expression and feeling, including a sense of impending death, which is characteristic of the severer forms of angina pectoris. Pain of this kind is apt to be associated with disease of the muscular substances of the heart, of its blood-vessels, and of the aortic valves. Pain is less common in mitral disease, and when present is more likely to be of a dull, aching character.

5. Dropsy.—Dropsy is the last of the symptoms characteristic of heart disease. It does not occur with every form of heart disease, being for the most part absent in disease of the aortic valves and most common in mitral disease. Not every case of mitral disease is associated with dropsy, but it occurs sooner or later in the vast majority of cases. Very rarely it is the first symptom noticed, and first makes its appearance almost invariably in the lower extremities. It is the direct consequence of backing of the blood into the venous side of the circulation, and is due to the transudation or filtration of its watery elements. The serum is, as it were, strained out. When unchecked, the swelling extends from the feet to the legs, thighs, the trunk, abdominal walls, and, last of all, serous cavities and especially the peritoneal cavity, producing ascites. The pleural sacs may, in rare instances, be the first seats of transudation in heart disease. (See remarks on Hydrothorax, page 548.) These simple transudates are usually free of albumin, as contrasted with inflammatory exudates.

DISEASES OF THE PERICARDIUM.

ACUTE PERICARDITIS.

Definition.—An inflammation of the serous covering of the heart and of its reflection on the inner surface of the pericardial sac.

Etiology.—By far the larger number of cases of pericarditis are due to some toxic substance in the blood, such as is developed in the infectious diseases, or to some excrementitious matters which accumulate in the blood

because of deficient elimination. Other cases arise *per contiguum*, a few cases are traumatic, and those that cannot be accounted for are called idiopathic. Acute articular rheumatism or its cause is by far the most frequent etiological factor, from 30 to 70 per cent. of all cases being ascribed to it. The greater the severity of the primary disease, the more likely is it that the complication, pericarditis, will occur; yet it arises also in the mildest cases, and has sometimes even preceded the rheumatic attack. It may be that certain seeming idiopathic cases are due to the toxin of rheumatism spending itself on the pericardium instead of on the joints. Other infectious diseases causing it are pyemia, scarlet fever, typhoid fever, diphtheria, and even measles. Bright's disease is one of the best recognized causes of pericarditis, and it is probably the excrementitious matters which accumulate in the blood in this disease which are responsible for it. Such dyscrasic states of the blood as are represented by scurvy and pupura hæmorrhagica play an important part in its production. Tuberculosis of the pericardium is a common cause of pericarditis. Tubercular pericarditis may be part of a general tuberculosis or a secondary infection from the lungs.

Diseases of adjacent organs which cause pericarditis are chronic valvular disease, pleuropneumonia, pleurisy, especially tubercular pleurisy, morbid growths in the vicinity, ulcerative disease of the esophagus, disease of the bronchial glands and bronchi, disease of the vertebræ, ruptured aneurysm, abscess of the heart, or invasion of the pericardium by suppuration through the diaphragm.

Morbid Anatomy.—The appearances vary with the stage of the disease. Ordinary acute pericarditis is met with in one of three stages. The *first stage* is represented by hyperemia and its consequences. The initial events are hyperemic redness, followed by roughness caused first by loosening and detachment of the epithelium, and further increased by deposits of fresh inflammatory lymph. This lymph is spread at first in yellow flakes over the surface of the pericardium.

From this point onward morbid appearances vary with the mode of termination. This may be by resolution, when the products described undergo fatty degeneration and are absorbed, restoring the normal state. More frequently there supervenes the *second stage*, in which the liquid transudate increases, separating the two surfaces of the pericardium and distending the sac. This transudate is a clear, straw-colored fluid in which may be found floating flakes of lymph above described. The quantity of fluid varies greatly, amounting sometimes to a liter (2 pints) or more. In favorable cases it, too, is reabsorbed, and the two pericardial surfaces are reapposed with or without union of the opposing surfaces. Sometimes this union is complete, so that the two surfaces are separated, with difficulty, or it may be partial, by bands of varying length. At other times the second stage is represented by immediate organization without intervening transudation—primary adhesive inflammation.

The term *third stage* is usually applied to the phenomena succeeding the transudation described. They include organization or suppuration. The former may be adhesive in various degrees or villous. The latter occurs when, union being apparently prevented by the constant motion to which the two surfaces are subjected, organization takes place without attachment of the opposing surfaces, and a peculiar villous product results, characterized by numerous projections, uniform in size and shape, resembling closely the papillæ on a sheep's tongue. These papillæ, composed of vascular connective

tissue, originate in the usual way by an outgrowth and vascularization of the connective tissue of the serous membrane, and not by organization of the exuded lymph, as was formerly supposed. This lymph undergoes fatty degeneration and absorption.

The more unfavorable cases terminate in suppuration, which may also be primary or secondary. In the former instances there is at once a rapid outwandering of leukocytes and the formation of a purulent fluid in the pericardium—pyopericardium. In the secondary form the clear, serous transudate is substituted by pus, an event which is usually ushered in by a chill and is followed by hectic fever. The cause of the suppuration in either case is the access of the usual pus organisms, the streptococcus and the staphylococcus. The contents of the pericardium may become cheesy, especially if the inflammation is tubercular.

Symptoms.—Clinically, as well as anatomically, we seek to separate the stages, first of roughening, second of effusion, and third of absorption or organization, chiefly by aid of the physical signs.

Pericarditis is sometimes ushered in by a *chill*. More frequently a sharp *pain* in the region of the heart initiates the attack, previous to which there may, however, have been a sense of *discomfort* or distress about the organ, which may, indeed, be the only subjective symptom. The pain and discomfort may be referred to the epigastrium. To these symptoms may be added *dyspnea* or orthopnea. There is also *fever*, which is not very high—temperature 102° F. (39.9° C.)—unless there be previous disease with fever, when the pericardial complication adds an increment. The *pulse* is frequent and the patient restless and uncomfortable. There is often *tenderness* over the region of the heart, which may be brought out by percussion or pressure with the stethoscope. The *position* assumed by the patient varies: sometimes he may prefer to lie on the affected side, at other times on his back or on the right side, or he may prefer to sit up. Finally, there may be no subjective symptoms added to those of the primary disease, in which case the pericarditis must be discovered only by the physical examination, or it may escape detection altogether until the necropsy reveals it.

As the effusion distends the pericardium and encroaches on the lung, the difficulty in breathing increases, dyspnea becomes more marked, the action of the heart more disturbed, frequent, and irregular. When very large, it may press upon the left lung. It may even influence the percussion note in the upper lobe below the clavicle, causing there a tympanitic note—Skodaic resonance—by indirect relaxation. Much more frequently the lower lobe is compressed, sometimes completely emptied of air, whence the percussion note in the lower axilla and about the angle of the scapula may be Skodaic or impaired in resonance or even absolutely dull. The breathing sounds may be feeble, broncho-vesicular, more rarely bronchial, and there may be egophony. These signs are not to be confounded with those due to pleuritic effusion, which are characterized by diminished or absent tactile fremitus, which is not the case in compression by a distended pericardial sac, where it is rather increased. Attention was called to these symptoms as far back as 1857 by H. Bamberger, whence they are known as Bamberger's sign.* The normal state of the lung may be in part restored by changing the position of the patient, causing him to lean forward, lie on his right side, or assume the knee-elbow position.

* "Lehrbuch der Krankheiten des Herzens von H. Bamberger," Wien, 1857.

William Ewart has called attention to signs similar to those described by Bamberger below the right mamma; also to an area of dullness below the ninth rib between the spine and a line drawn through the angle of the scapula and to a less degree to the right of the spine. In this area, known as Ewart's posterior pericardial patch of dullness," the respiratory sounds are also absent and the voice sounds are feeble. He ascribes this sign to an altered dorsal relation of the liver due to pressure of the pericardial effusion. Ewart has also called attention to what he calls the "first rib sign," also recognized by palpation. The upper edge of the first rib may be followed round by the finger tip, because the clavicle is apparently raised above its normal position, by the effusion, which must of course be large.

Still larger effusions produce *dysphagia* in consequence of encroachment on the esophagus. *Aphonia* may occur from pressure on the recurrent laryngeal nerve. The pressure of the full sac on the aorta may produce the *pulsus paradoxus* of Griesinger and Kussmaul, in which the pulse beat is weakened and accelerated during inspirations.

A certain degree of prominence of the epigastrium may result from the encroachment of distended pericardium, while the excursion of breathing movement may be noticeably greater on the right side.

Fig. 51.—Pulsus Paradoxus.

Influence of Respiration upon the sphygmogram (after Riegel); I, During inspiration; E, During expiration.

Physical Signs.—In the *first stage* there may be pain in response to pressure, but the physical sign characteristic of this stage is the friction sound. It may be associated with an impulse stronger than natural. The friction sound is of the greatest importance in diagnosis. It is a superficial to-and-fro sound heard directly under the ear, commonly loud and rasping, never blowing, sometimes creaking. *It is loudest over the middle of the heart.* It is not conducted as are the murmurs at the valves in the direction of the blood current. It is often influenced by changes of position or by breathing. The rub may sometimes be felt by the hand placed over the heart. In the first stage, at least, it lasts a short time,—a day or two at most and sometimes only a few hours,—and disappears with the filling of the pericardium by effusion. It may sometimes be brought out or intensified by having the patient lean over on the stethoscope.

The *second stage*, or that of effusion, exhibits usually, but not always, signs discoverable to *inspection* or *palpation*, or to both. They depend on the amount of effusion. If large, the precordium may be bulging, the interspaces obliterated, and the impulse undulating, tumultuous, and indistinct. As the effusion increases the heart is pushed further and further away from the chest-wall and assumes a more horizontal position, while the impulse, feebler and feebler to vision and touch, may disappear altogether. *Percussion* furnishes the most striking change. The area of dullness is enlarged—peculiarly enlarged. It becomes rudely triangular or truncated pyramidal with the apex toward the inner end of the left clavicle and the base as low as the

seventh rib, and extending in extreme cases from nipple to nipple, even pushing the diaphragm and liver downward. The absence of resonance in the fifth intercostal space, to the right of the sternum, is known as Rotch's sign in pericarditis, and has been assigned considerable diagnostic value. It is not impossible, however, that a similar dullness may be caused by a circumscribed pleuritic effusion or even great enlargement of the heart. The cardio-hepatic angle as determined by percussion, normally an acute or a right angle, may become obtuse. *Auscultation* confirms palpation. The conditions of friction sound are removed more or less by separation of the opposed pericardial surfaces. Yet the sound does not always disappear. The heart-sounds are indistinct and best heard at the top of the sternum. Sometimes there is a basic systolic murmur.

The *third stage* represents a return to the normal state of affairs, which may come about with the intermediation of a *friction redux* or not; or adhesions may form between the heart and the sac, embarrassing its movements permanently, and producing retraction of the chest-wall with systole. On the other hand, necropsy has often revealed close adhesions between the heart and the pericardium which were not suspected during life. Permanent roughening, represented by the "sheep's tongue" surface or other roughening or adhesions, may produce permanent friction sound, and the pericarditis is chronic.

Physical Signs of Chronic Adhesive Pericarditis or Adherent Pericardium.—These differ materially. They are most easily studied in children, in whom the condition is especially apt to occur after rheumatism. Their study is further facilitated by dividing the condition into two groups:

1. *Simple adhesion of the pericardial and epicardial layers.* These are the cases more frequently overlooked, sometimes giving rise to no symptoms and first found at necropsy.

2. *Adherent pericardium, with chronic mediastinitis and fusion of the outer layer of the pericardium with the pleura and to the chest-walls,* a serious form, leading to marked hypertrophy and dilatation, especially in children. To *inspection* and *palpation* the precordium is bulging, the impulse is more diffuse, extending sometimes from the third to the sixth interspace, and from the right parasternal line to outside the left nipple. The *apex* may be *displaced* in various degrees from its natural site; it may be to the right of its normal position and above it or down toward the epigastrium. It is sometimes multiple, or spreads in a wave-like manner over the area named. At other times the systole is associated with a *tugging retraction of the chest-wall*, which is especially evident in thin persons and is regarded by some as the most valuable sign of adhesion of the pericardium. It is most frequently noted between the seventh and eighth ribs in the left parasternal line. This may be followed by a rapid rebound of the chest-wall, known as the *diastolic shock*. It may be associated with a coincident collapse—the *diastolic collapse of the cervical veins*, due to a sudden emptying of these vessels consequent on the expansion of the chest-wall, a sign first described by Friedreich. Broadbent's diaphragm sign has recently attracted much attention—a systolic tug which is communicated through the adherent diaphragm to its points of attachment, especially on the left side behind, between the eleventh and twelfth ribs. It is distinct and apart from the tugging in the left parasternal line, between the seventh and eighth ribs, to which attention had been previously called. Furthermore, owing to the attachment of the pericardium to the central tendon of the diaphragm this muscle does not descend with

inspiration, and consequently the usually visible movement of the epigastrium during this act does not take place.

It is in adhesive pericarditis, too, that we sometimes have the *pulsus paradoxus*, referred to on page 562. First, Griesinger, and later Kussmaul, called attention to it as a constant symptom of cicatricial mediastinitis, due to the dragging of the cicatricial tissue on the great vessels during inspiration. It happens, too, when the great vessels, already compressed by the exudate, are further encroached upon by the expanding lung, making the pulse smaller and more frequent. This is more frequently demonstrable by the sphygmograph, but in extreme cases may be appreciated by the finger. It is not a pathognomonic sign of either event, but if associated with an inspiratory distention of the cervical veins, it points strongly to adhesive pericarditis.

To *percussion* there is usually a large increase in the normal area of cardiac dullness, commonly upward and to the left, sometimes as high as the first interspace. Often the pericardium is adherent to the adjacent pleura, in which event the area of cardiac dullness is not influenced by deep breathing, a sign pointed out by C. J. B. Williams as of great value in diagnosis.

Auscultation may be entirely negative, or there may be a modification of the usual friction sound which closely resembles the creaking of leather. A galloping or fetal rhythm may be present, or there may be a loud systolic murmur at the apex, which has often given rise to the erroneous diagnosis of mitral valve disease, being due to relative insufficiency. Endocardial disease may, however, coexist, especially in children. A presystolic murmur is sometimes heard.

The possible association of chronic adhesive pericarditis and mediastinitis with proliferating peritonitis, perihepatitis, and splenitis should be remembered.

Diagnosis.—In all cases of acute articular rheumatism the heart should be frequently examined, because pericarditis often supervenes with feebly pronounced subjective symptoms. At the outset the distinction is to be made between pericarditis and *acute endocarditis*, which even more frequently succeeds on rheumatism with subjective symptoms no more distinctive. There is usually not much difficulty in acute cases. The to-and-fro rhythm, heard directly under the ear, usually most distinct over the center of the heart, and the absence of sounds transmitted in accordance with the laws of transmission of the valvular abnormal sounds, are distinctive features of the cardiac friction. If, however, one of the to-and-fro elements is wanting, the difficulty is greater and errors do occur. Close study must be made as to transmission. It is further characteristic of the friction sound that it is increased in loudness by pressing the chest-wall with the stethoscope, while this is not the case in endocardial murmurs. Such pressure is, however, often painful to the patient. In *chronic valvular defects* there are changes in the size and position of the heart which are not present in the first stage of acute pericarditis. When both acute endocarditis and pericarditis are present, the difficulty is greatly increased and one or the other condition is likely to be overlooked.

The "pleuropericardial" friction sound or "extra-pericardial" friction sound is to be distinguished from pericardial friction sound. It is a sound similar in rhythm to the pericardial sound, but the primary conditions of its causation are in a pleuritis involving the opposed surface of the mediastino-costal sinus of the left side. It is more commonly heard, therefore, over the left border of the heart. It is the combined product of the respiratory and

cardiac action, being usually louder during expiration. It generally ceases during a deep inspiration, because at this time the cardiac action cannot produce the required rubbing. On the other hand, this is sometimes the very condition under which the friction sound is loudest. Simply holding the breath may also stop it, though not necessarily, because the heart motion produces it. This influence of the breathing one way or the other is, however, of importance in diagnosis, while other symptoms must also be taken into consideration. Thus, if it be a pleurisy, the pleural friction sound is probably heard elsewhere, and there are the other symptoms of a pleurisy present, while those of a pericarditis are absent. Unlike the true pericardial friction sound the pleuropericardial friction sound is uninfluenced by bending the body forward, but is heard with equal distinctness with the body in any position. Difficulties again increase when it is associated, as it sometimes is in a pleuro-pneumonia, with endocarditis. It also occurs in tubercular phthisis, where it is sometimes associated with a systolic click due to the simultaneous expulsion of a bubble of air from a portion of softened lung.

For diagnosis between pericarditis with effusion and dilatation of the heart see page 605. It is in this differential diagnosis particularly that Rotch's sign and the difference as determined by percussion of the cardio-hepatic angle become valuable. It must be remembered, however, that Rotch's sign is not always present, even when there is considerable effusion. The possibility of a circumscribed pleuritic effusion must also not be overlooked. Bamberger's sign—dullness in the region of the angle of the left scapula—should be sought; also Ewart's posterior pericardial patch.

Prognosis.—The course of pericarditis varies with different cases. In an ordinary uncomplicated case passing to recovery, the duration is one to three weeks, even when there is considerable effusion, which is often absorbed with surprising rapidity. In other cases, especially in cachectic subjects, the duration is longer. Relapses occur. When adhesion results, convalescence is greatly prolonged, and in many cases the heart is permanently crippled. On the other hand, extensive adhesions are sometimes found at necropsy where no lesion was suspected. The pyopericardial cases are usually fatal.

Treatment.—Prompt treatment is of the greatest importance in pericarditis. Rest is an absolutely essential condition. As soon as the diagnosis is made, a blister is of the greatest value. There is no other disease in which I am so satisfied of the efficiency of a blister. It should be at least three inches (7.5 cm.) square. I am confident that it helps to prevent effusion and also to promote the absorption of effusion. Along with this, measures to relieve pain are indicated. Nothing is so satisfactory as moderate doses of morphin administered hypodermically, associated with atropin in the proportion of 1-150 grain (0.00044 gm.) of the latter to 1-4 grain (0.0165 gm.) of the former. Cold applications to the pericardium by Leiter's coil or the ice-bag are sometimes useful. At other times hot applications are more comforting.

Digitalis in moderate doses is usually indicated to steady the heart at its work, without, however, stimulating it too forcibly. For the same reason alcohol and ammonia, especially the aromatic spirit of ammonia, are indicated. Strychnin is a valuable heart tonic. Liquid food, including milk and broths, should be adhered to until convalescence is established. Eggs may, however, be early allowed.

If the effusion is very large, tapping the pericardium may be necessary

to relieve the patient, although practically the relief which first follows a successful operation is rarely followed by complete recovery. The aid of the surgeon should be secured if possible, but if not, puncture may be made in the fourth interspace, an inch (2.5 cm.) to the left of the edge of the sternum. If made in the fifth interspace, the puncture should be made a little further out—say 1 1-2 inches (3.5 cm.). A safe point which may be used in large effusions is the left xiphocostal angle, at which the needle should be pushed upward and backward. When the pericardial fluid is pus, a simple tapping is insufficient. Free incision should be made, and free drainage should be established with aseptic precautions. John B. Roberts* collected thirty-five cases of suppurative pericarditis treated by incision, of which fifteen recovered and twenty died. It is not impossible that if operation were done earlier, better results would follow.

The treatment of chronic adhesive pericarditis is mainly symptomatic, and directed to building up the strength of the patient.

OTHER PERICARDIAL AFFECTIONS.

Other affections of the pericardium are hydropericardium, hemopericardium, pneumopericardium, and tuberculous pericarditis, rarely morbid growths.

Hydropericardium.—This term is applied to a large accumulation of serous fluid in the pericardium. In health the pericardium is simply lubricated by this fluid: It occurs sometimes as a part of a general dropsy, most frequently cardiac dropsy, more rarely in renal dropsy. The accumulation is seldom large in these cases. It is not common, but is sufficiently so to demand frequent examination of the heart, as it is often overlooked. Its signs are the same as those of the inflammatory effusion.

Hemopericardium, or blood in the pericardium, occurs only as a result of rupture of an aneurysm in the first part of the aorta into the pericardial sac, from rupture of the heart itself or a wound of the heart. It is rapidly followed by shock and death. Its physical signs are those of effusion. Cancer of the pericardium may be associated with blood effusion. It may also be caused by tuberculosis of the pericardium.

Pneumopericardium, or gas in the pericardial sac, is a rare condition, analagous to the much more common one of pneumothorax. As in pneumothorax, the presence of air implies also the presence of liquid, and that, usually, pus. It is produced by similar causes, such as perforation into an air-containing space like the lungs or esophagus. Such perforation is usually traumatic. Decomposition of pericardial exudate or morbid growth, it is said, may also produce it.

Symptoms.—Its symptoms are pain and pericardial embarrassment, but the physical signs are most distinctive, especially those of auscultation. To inspection there is prominence of the precordium, with indistinctness or obliteration of apex-beat, restored by the patient's bending forward. Percussion furnishes dullness over the lower portion of the cardiac area and tympany above it, the position of both being altered by change in position of the body. To auscultation the heart-sounds assume a striking metallic character, being audible even at a distance from the body. A similar

* "American Journal of the Medical Sciences," December, 1897.

metallic character is given even to a friction sound, if it is present, as it often is.

Diagnosis.—The diagnosis of this condition requires differentiation from the effect of an *air-dilated stomach* on the heart-sounds, or rarely of a *phthisical cavity* or *pneumothorax*. All doubt in the case of the stomach is removed by filling it with water. The associated symptoms of the other conditions make a mistake unlikely.

Treatment is scarcely available, except in case of external injury, when operation may be of service.

TUBERCULOUS PERICARDITIS presents nothing peculiar in its symptoms or signs as already described.

MORBID GROWTHS OF THE PERICARDIUM are rarely diagnosed before death.

DISEASES OF THE ENDOCARDIUM.

ACUTE ENDOCARDITIS.

SYNONYM.—*Valvulitis*.

Definition.—Endocarditis in both its acute and chronic forms is an inflammation for the most part confined to the valves; for such inflammation, therefore, *valvulitis* is a more correct term. The lining of the cavity of the heart is, however, sometimes affected in acute endocarditis, especially in the more severe cases, when it is known as *mural endocarditis*. It is usually in the apex of the left ventricle that such inflammation occurs.

Etiology.—All cases of acute endocarditis in the light of modern studies must be regarded as infectious—that is, as due to a specific poison commonly associated with some disease which is regarded as the cause of the endocarditis. Acute rheumatism is the best recognized and most frequent of these. Upon this follow closely the infectious fevers, with their various specific organisms or their toxic products. In the disease which is acknowledged to be the most common cause—acute articular rheumatism—no causing organism has as yet been found.

There is, however, a great difference in the severity of different cases of acute endocarditis, and the disease is easily separable into two classes, from one of which recovery almost always takes place up to a certain point, leaving often a degree of valvular defect known as chronic endocarditis, while the other is invariably fatal. The first, or milder, of these classes was for a time ascribed to some specific non-organized agency, even after the more severe and fatal form was recognized as infectious, whence arose the terms simple endocarditis on the one hand, and infectious, ulcerative, malignant, or mycotic on the other.

In attempting to explain why at one time the simple form and at another the virulent form of endocarditis arises, it may be stated that the toxins generated by the less virulent bacteria pave the way for the operation of the virulent streptococcus and staphylococcus pyogenes, the pneumococcus, the gonococcus, and other organisms which are found in the morbid products of malignant endocarditis. It is not unreasonable to suppose that the former produce the simple form of endocarditis, while the co-operation

of the septic bacteria named is necessary to produce the malignant variety. On the other hand, it may be not so much the specific organism as the constitutional or local peculiarities of the individual on whom the disease is engrafted—the nature of the soil, as it were.

THE MILD OR SIMPLE FORM OF ACUTE ENDOCARDITIS.

SYNONYM.—*Warty or Verrucose Endocarditis.*

Etiology.—Almost any one of the recognized infectious diseases may become a cause of simple endocarditis. Acute articular rheumatism is, however, the most frequent cause, 20 per cent. of all cases being ascribed to it. After this comes *chorea*. Indeed, William Osler, who has made the subject a special study, says: "There is no disease in which, postmortem, acute endocarditis has been so frequently found." Vegetations were found on the valves in sixty-two out of seventy-three fatal cases of chorea collected by him. This fact has suggested even a microbic origin of chorea, which is sustained by other features in the history of the disease, but not by actual demonstration. In the absence of such demonstration, chorea must be regarded in the light of a predisposing cause. Scarlet fever, pneumonia, tuberculosis, and peliosis rheumatica are not infrequent predisposing causes; less frequently are tonsillitis, diphtheria, erysipelas, smallpox, and typhoid fever. Endocarditis also supervenes as a complication of Bright's disease. Even in these cases bacteria are found in the vegetations. Cachectic states, such as are caused by tuberculosis and cancer, also seem to favor the development of acute endocarditis. Finally, chronic valvulitis is a predisposing condition to simple acute endocarditis as well as to the malignant form, being often complicated by acute attacks, whence the term "recurring" endocarditis.

Morbid Anatomy.—The left side of the heart is more frequently involved, and in this the mitral leaflets first, in at least half of all cases; next the aortic cusps; then, in the right heart, the tricuspid valve, and finally the pulmonary valve. In embryonic life, in which acute endocarditis also occurs, the right side of the heart and the tricuspid valve are most frequently affected, accounting thus for certain congenital valvular defects.

The type of the morbid change on the valves in simple endocarditis is so constantly a product warty or fungous in appearance that the term *warty* or *verrucose* endocarditis is often applied to this form. On the auricular surface of the mitral, and the ventricular surface of the aortic valves, at the line of their contact during closure,—*i. e.*, 1-25 to 1-12 inch (1 to 2 mm.) back of the valve edge.—granular and warty excrescences make their appearance. These rise 1-12 to 1-8 inch (2 to 3 mm.) above the surface and extend a variable extent along the valve. They soon become capped with fibrin, often abundantly, and thus a vegetation is formed. The vegetation begins in a proliferation of the cells of the adventitia and of the connective tissue of the external laminae of the endocardium. Thus formed, it is a friable product, liable to be broken off at any time and carried into the general circulation to a point of lodgment, where it plays the rôle of an embolus. In point of fact, this accident does not often happen in the simple acute endocarditis succeeding febrile diseases. It occurs more frequently in the acute endocarditis engrafted on chronic valvular disease, and in the malignant form. More frequently the vegetation undergoes organization

and contraction, and the valve is restored partially to its natural condition, leaving a simple sclerotic thickening, which is especially prone to become the starting-point of new processes. But not every aortic murmur in the course of rheumatism implies endocarditis, as the condition of the blood predisposes to a hemic murmur; nor every murmur at the apex, because the state of the muscle predisposes to imperfect closure of the auriculo-ventricular orifice. Unless there has been previous valvular disease, there is no enlargement of the heart in acute endocarditis.

Symptoms.—These are often masked by those of the previous disease, and sometimes overlooked, the autopsy first disclosing the lesion. There is frequently noticed, however, greater or less *embarrassment of breathing*, orthopnea being not infrequent; the *pulse* is much more rapid and may be *irregular*, the patient is restless, the countenance dusky, while the *temperature* is a degree or two higher than normal. Altogether, it is plain that he is sicker. Yet there is rarely acutal pain, as in pericarditis.

Physical Signs.—In the first attacks of endocarditis there is no notable enlargement of the cardiac area as determined by percussion or inspection of seat of apex-beat. *Auscultation* may recognize a murmur, of which the situation varies with the valve involved. If the mitral, a murmur is heard in this area, usually systolic, soft, and blowing, at times quite harsh. Very rarely is there a presystolic murmur, though its more frequent occurrence might be expected from the nature and situation of the lesions described. When the lesion is at the aortic orifice, the murmur is heard in the aortic area at the second interspace at the right edge of the sternum. It is usually also systolic, but may be diastolic. But not every murmur heard in acute endocarditis is due to a valvular lesion. Basic murmurs also occur in the pulmonary area to the left of the sternum, which are functional in nature—the bellows murmur.

A systolic murmur in the mitral area is not always due to regurgitation. The same excrescences which grow on the valve leaflets may also attach to the papillary muscles and chordæ tendinæ as well. Mitral regurgitation may also occur in rheumatism and in other acute febrile diseases from myocardial changes, as the result of which the basal part of the cardiac muscle is enfeebled and unable to do its part of the work of closing the mitral orifice, and the valve leaflets are insufficient to complete it. Some of the cases of murmur which disappear with recovery may belong to this category. It is characteristic of endocardial murmurs to come and go.

Diagnosis.—This is based almost entirely on the physical signs, as no one of the symptoms is pathognomonic. Nor are the murmurs always to be relied upon, for the reasons assigned.

The distinction of the endocardial from the pericardial murmur was considered in treating of *pericarditis*. The more superficial situation of the latter over the body of the heart, its to-and-fro rhythm, not connected with the heart-sounds, its failure to follow the usual laws of conduction, and the fact that it is made more pronounced by pressure—all serve to distinguish it. A. E. Sansom calls attention to a possible source of error in a pericardial roughening at or about the apex, especially in children, which causes a systolic apical murmur. This should be remembered as a possible, but rare, occurrence.

Prognosis.—The subject of the simple form of acute endocarditis rarely dies, but he is likely to recover with a damaged heart—in other words, chronic valvular disease results. This is not, however, always the case,

for complete recovery is not impossible. On the other hand, some of the instances of complete recovery after mitral regurgitant murmur belong doubtless to the category described of insufficiency due to myocardial defect without mitral lesion. It should not be concluded, however, that because a murmur has disappeared the patient has certainly recovered, since a murmur due to myocarditis may be succeeded by another true valvular murmur. Finally, one acute attack from which recovery has taken place is liable to be succeeded by another and another, so that, sooner or later, chronic valvular defects are produced.

Treatment.—The keynote of the proper treatment of simple acute endocarditis is absolute quiet. It is not often that much else is required. A blister is not of the signal service here that it is in pericarditis, while digitalis is not indicated unless there is irregularity, when the dose should be moderate—only enough to steady the heart. Dyspnea is best treated by sufficient doses of opium or morphin, which should not be put off too long. The diet should be easily assimilable and liquid until convalescence is established.

THE SEVERE OR MALIGNANT FORM OF ACUTE ENDOCARDITIS.

SYNONYMS.—*Ulcerative, Infectious, Mycotic, or Diphtheritic Endocarditis.*

Definition.—Malignant endocarditis is an acute infectious fever due to inoculation of the blood by a bacillus or its toxic products, and characterized locally by a specific valvulitis. It is called primary when not engrafted on some other infectious disease.

Historical.—It was recognized as a separate form of disease in 1851 by Senhouse Kirkes, and further studied by Charcot and Velpeau, in France, Virchow in Germany, and recently in this country by William Osler, who made it the subject of his Gulstonian Lectures before the Royal College of Physicians, England, in 1885. Its mycotic nature was not suspected until after Koch discovered the bacillus of tuberculosis, in 1882.

Etiology.—Malignant endocarditis shares with the simple form an infectious origin. No satisfactory explanation has, however, been furnished of its more malignant nature. Mention was made when treating of the simple variety of the suggestion sustained by the experiments of Wyssokowitch, Ribbert, Orth, and others, that a state of the blood due to the toxic effect of bacteria may be the cause of the simple form, and that it may afford conditions favorable for the operation of the more virulent bacteria found associated with the malignant form. It is extremely doubtful whether there can be a primary malignant endocarditis without the intervention of some one of the diseases which usually precede it. The presence of chronic valvular defects affords the most important predisposing cause favoring the action of the causes of the acute malignant form. Goodhart found it in 61 out of 69 cases, and Osler in 54 out of 209. The latter also found it 11 times at 100 autopsies of fatal cases of pneumonia. Of the infectious diseases associated with the malignant form of endocarditis, pneumonia is the most frequent. The disease occurs also in association with gonorrhœa, rheumatism, peliosis rheumatica, pleurisy, puerperal fever, bone necrosis, and septicemia from any cause. More rarely it has been found in connection with meningitis, smallpox, diphtheria, scarlet fever, tuberculosis, and dysen-

tery. Most frequently, perhaps, the micro-organism is the lancet-shaped bacillus of pneumonia; after this, pus organisms, the streptococcus and staphylococcus.

Morbid Anatomy.—As to the acute cardiac lesions associated, we find, either alone or in addition to the old sclerosis, three sets—*vegetative*, *ulcerative*, and *suppurative*. The vegetative are for the most part made up of closely-packed spherical micrococci, more or less commingled with small fibrin masses. The vegetations vary in size from that of a pin's head to that of a pea, and are reddish-yellow in color. The seat of this vegetation becomes rapidly necrotic, and breaks down into an ulcer which may perforate the valve, with or without previous protrusion—the so-called *valvular aneurysm*. More rarely minute foci of pus are found in the deeper tissues of the valve leaflets. The invasion is, however, not always confined to the valves, but may extend to the mural endocardium. Of the valves, the mitral is most frequently involved; next, the aortic; next, mitral and aortic jointly; next, the lining of the heart-wall; next, the tricuspid; and last, the pulmonary valve. In a few instances the right heart alone is invaded. Other morbid changes include the lesions of the concurrent affection and the phenomena of embolism due to lodgment of fragments of the vegetation. The result of the latter when complete is a metastatic abscess, though the earlier stages of red infarction may also be present.

The spleen, kidney, skin, and even the cerebral cortex may be seats of embolism. In addition to these, we may also have embolism and hemorrhagic infarct occurring in the lungs from emboli starting in the right heart, as contrasted with those originating in the left heart which lodge in the systemic circulation. The number of embolisms varies greatly in these cases. They may be altogether absent, while they may be counted by hundreds, in which event they are, of course, very small. The spleen is enlarged even when not the seat of embolism, as in other infectious diseases.

Symptoms.—Given a pneumonia, pleurisy, the puerperal process, or any one of the diseases named, with the supervention of *chills*, followed by *fever* and *sweats*, this form of heart disease should be immediately thought of and the organ carefully examined for the auscultatory signs of endocarditis. In the primary form, however, should this exist, we have not even the presence of one of the diseases named to suggest the occurrence of ulcerative endocarditis. In this form, particularly, the resemblance to intermittent fever seems at first close, but a careful study of the temperature chart from day to day, and, above all, utter failure of the antiperiodic remedy to produce any effect, will in a short time show that the malarial disease is not present. Doubtless, often the malady under consideration has been mistaken for intermittent fever, and not without reason, for many a case of irregular quotidian and tertian fever presents similar symptoms; but the regular, almost rhythmical, rise and fall of temperature, as exhibited in the chart of an intermittent fever, is wanting. Indeed, I think there is no disease in which the extreme irregularity in temperature reaches that of the one under consideration, as a careful study of the appended temperature chart from a case of my own in the University Hospital will show. Note that the maximum is reached at any time of day or night. Yet the temperature is not always so high, nor is the extreme range always so great as here indicated. The absence of the *plasmodium malarie* serves only to distinguish it from malarial disease.

It always greatly aids the diagnosis when to chills and fever are added

other symptoms suggesting *embolism*, which so frequently occurs. The occurrence of a *hemiplegia*, pain in the region of the spleen, with increased dullness on percussion, pain in the region of the kidney with *hematuria*, or a *sudden blotch in the skin*, of the kind described, is of inestimable value. Rarer symptoms of similar origin are *impaired vision* from retinal hemorrhage, *parotitis*, and *abscess of the parotid gland*. The symptoms are not always so pointed as detailed, while they may include others not mentioned. The fever may not be so high, but it is always present; again, it may not

Fig. 52.—Temperature Chart, Malignant Endocarditis.

be remittent, but continuous. There may be *jaundice*, *precordial oppression*, *shortness of breath*, while heart symptoms may be altogether absent, when it is almost impossible to distinguish the disease from a septic fever of the ordinary kind. The *pulse* and *respirations* are invariably accelerated. Extreme embarrassment of breathing is very characteristic. *Albuminuria* and *casts* occur in all forms, either as the result of acute nephritis or of renal embolism.

A further study of the symptoms of malignant endocarditis permits

their classification into three groups, known as the *septic* or *pyemic*, the *typhoid*, and the *cerebral*.

The *septic* type occurs in connection with such septic processes as external wounds, the puerperal process, or acute bone disease with necrosis. The symptoms added are rigor, irregular fever, sweats, and exhaustion. Yet these are only the symptoms characteristic of pyemia. In fact, it is a pyemia; and the term *arterial pyemia*, suggested by Wilkes, is a good one, because the pyemic abscesses result from emboli, starting in the left heart and lodging in arteries. The endocarditis constitutes the distinctive feature of the disease. The resemblance to intermittent fever here exists also, and a quotidian or double tertian type may be simulated. It is in this form especially that leukocytosis occurs, determined by a blood count.

The symptoms of the *typhoid* type are even more characteristic. We meet here, too, the same prostration, irregular temperature, and sweating; rigor is less frequent, and the onset is more gradual. There are delirium, drowsiness, often diarrhea, with distention of the abdomen and tenderness in the right iliac region, to which a rash may also be added, which, though not identical with that of typhoid fever, is, nevertheless, similar to it. The tongue is dry and brown, and sordes collects about the teeth. The temperature is remittent, like that of typhoid, reaching 103° F. to 104° F. (39.4° C. to 40° C.) and even higher. Here again the heart symptoms may be overlooked.

Still another group is the *cerebral*, in which the symptoms simulate meningitis, basilar or cerebrospinal, with acute delirium as the distinctive feature.

Physical Signs.—If there is anything peculiar about the physical signs, it is their want of definiteness. When murmurs are present, it is often difficult to locate or time them precisely. They often vary from day to day. They may occur at both base and apex, and with reason, for both sets of valves may be and often are involved. The superaddition of pericarditis adds a further source of confusion in the friction sound superadded. If chronic valvular disease exists, its signs are also present, including those of hypertrophy.

Complications.—As to complications, these are mainly the original cardiac disease or the diseases the specific organisms of which most frequently cause the virulent inflammation. Pericarditis and pleurisy are frequent complications in the strict sense of the term; there may also be meningitis. Acute nephritis, the result of sepsis and quite independent of embolism, may be present, with its characteristic symptoms, albuminuria, blood casts, and free blood-corpuscles. Gastro-intestinal derangements not of embolic origin are sometimes conspicuous. Diarrhea may be especially troublesome.

Diagnosis.—This is not always easy at first. A few days' study of the temperature, with its extreme fluctuations, the rigors, and the supervening sweats, should at once lead to suspicion, and these, if continued, point only to this disease. If one would always remember the possibility of the occurrence of malignant endocarditis in connection with the diseases named, it would be less frequently overlooked. The fever is a septic one in all cases, the heart symptoms adding the peculiarity. In true *typhoid fever* there is always splenic enlargement and often parotitis, so that the presence of these symptoms naturally suggests that disease, and an erroneous diagnosis is not inexcusable. It is said that splenic enlargement is not so marked as in typhoid fever, and that there is commonly more tenderness in

ulcerative endocarditis. This may be true in some cases, and not in others. So far as I know the Widal test has not been made in a case of ulcerative endocarditis.

Rheumatic fever often more closely resembles malignant endocarditis, with its high, irregular fever, and copious sweats, while confusion is further contributed to by the fact that endocarditis is one of the most frequent complications of rheumatism, the malignant form being, however, more infrequent than the simple. But recurring rigors are not usual in rheumatism. The joint symptoms of rheumatism are conspicuous at an early stage of the disease; there is no enlargement of the spleen, nor symptom ascribable to embolism, unless secondary to endocarditis. The essential identity of ordinary *pyemia* and malignant endocarditis has been mentioned, and only the endocarditis and its consequences distinguish the disease from ordinary septic fever.

It must not be forgotten that the simple and severe forms are not separated by any sharp line. The crucial diagnostic test is a bacteriological examination of the blood.

Prognosis.—The prognosis is always unfavorable, though ulcerative endocarditis may be prolonged for many weeks and even months. Usually, however, five or six weeks measure its course, while some cases are of shorter duration. Eberth reports a case fatal in two days.

Treatment.—Treatment heretofore has availed little. There seems reason to believe antistreptococcus serum may be of service, and several cases of cure are reported. Twenty c. c. may be injected daily. It seems quite harmless. The patient should be kept at rest. Remedies should be restorative and supporting—quinin, stimulants, digitalis. Nourishing food is indicated. The high temperature may be treated by sponging or by an ice-cap, or by Leiter's coils applied to the thorax or abdomen; but high temperature is seldom of so long duration as to require special treatment.

CHRONIC VALVULAR DEFECTS.

SYNONYMS.—*Chronic Endocarditis; Chronic Valvular Disease.*

Definition.—Permanent alterations in the structures about the cardiac orifices, producing incompetency, narrowing, or other deviations from the normal.

Etiology.—The majority of chronic valvular defects are the consequence of endocarditis, acute or chronic. It may be that the very first attack of acute inflammation has left the valve leaflets in so sclerotic a condition that they readily become the seat of the subsequent changes which constitute the chronic disease, or that several attacks may be necessary before a permanent effect is produced. On the other hand, we must acknowledge, too, a chronic valvulitis, in which valvular defect is brought about gradually without the intervention of acute inflammation. This process is analogous to chronic endarteritis, consisting in hyperplasia with fatty (atheromatous) and calcareous degeneration of the new tissue. In fact, a chronic endarteritis may spread from the aorta to the aortic valves. These slowly induced inflammations are variously caused. The rheumatic poison may cause them, as it does the acute forms. Alcoholic indulgence and intemperate eating, whether by the direct irritation of the substances taken into the blood or through the

poison of gout engendered by their use, are frequent causes. Another cause is prolonged muscular strain, producing overtension of the valve leaflets. This operates in laborers who do much heavy lifting, and sometimes in athletes. Especially potent is it when, as is often the case, hard muscular work is associated with overeating and drinking. To these, syphilis also often contributes a factor in some unknown way. Under all of these latter circumstances it is the aortic cusps which suffer most.

Morbid Anatomy.—The anatomical condition of the defective valves is made up of five separate factors, each of which may enter more or less into the lesion. This is true both of the auriculo-ventricular and semilunar valves. These conditions are :

(1) Thickening. (2) Retraction. (3) Adhesion. (4) Calcification. (5) Atheroma, either alone or associated with calcification.

1. *Thickening* is the immediate result of an overgrowth of connective tissue. The slighter degrees are seen along the bases of the aortic cusps and at the line of contact in closure of the mitral leaflets. Such degrees do not necessarily impair the function of the valves. More advanced stages produce a distinct thickening and sclerosis of the whole of each aortic cusp and mitral leaflet.

2. *Retraction* or curling is the result of shrinkage of this hyperplastic tissue. The three aortic cusps are often reefed back and fixed, although the very edge of the valve may still remain movable. In the case of the mitral valve, the tendinous attachments of the papillary muscles often contract and draw the valves into the left ventricle, producing a permanent funnel-like extension analogous to that which takes place in physiological closure of the mitral orifice.

3. *Adhesions* unite the valve leaflets, increasing their fixedness and rigidity, interfering with complete opening and closure. The right and posterior aortic cusps are most frequently united. Most serious is the effect of union of the mitral leaflets, which sometimes results in a reduction of the orifice to a mere slit or buttonhole-like opening—the buttonhole mitral orifice.

4. *Calcification* or limy infiltration of the valves thus united may succeed in various degrees, producing in extreme cases firm, bony rings which further diminish the mobility of the valves. In mild degrees there are formed splinter-like projections into the substance of the valve which also interfere with complete closure and opening ; at other times there may be simple marginal deposits which impede the function of the valves only slightly or not at all.

5. *Atheroma*, or fatty degeneration, is also often found in the shape of yellow spots on the surface of the valves and at the marginal attachments of the aortic cusp, without producing insufficiency.

Still another form of lesion found at necropsy is *rupture of a leaflet*, the result of strain. This is perhaps not possible with a sound valve, while one weakened by the morbid states described may give way. The physiological result is insufficiency, while the lumen of the orifice during systole is not encroached upon. Such an accident is not infrequent in acute ulcerative endocarditis in consequence of erosion and partial destruction of the valve.

Insufficiency of the aortic orifice at the time of life at which it is most common—say middle age—is favored by a gradual widening of this orifice from 4.5 inch (20 mm.) at birth to a possible 2 4.5 inches (70 mm.) at eighty years.

Congenital defects are relatively common to the right side of the heart,

which is the subject also of inflammations during intra-uterine life. The changes resulting from the latter are of the nature of fusions. Such defects also occur rarely on the left side; most rarely in the mitral valve.

MITRAL INSUFFICIENCY OR INCOMPETENCY.

Occurrence and Mechanism.—This is the most frequent of the uncombined forms of valvular disease. The valve leaks. The blood flows backward during systole from the left ventricle to the left auricle. The distended auricle, first attempting to resist the backward flow, hypertrophies but eventually dilates, and the blood is crowded backward into the lungs, which become engorged. The right ventricle, in its efforts to push the blood through the engorged lungs, hypertrophies, and the pulmonary factor of the second sound becomes louder and sharply accentuated. The compensating effect of the hypertrophied right ventricle for a time arrests the mischief. At this stage, perhaps, begins the hypertrophy of the left ventricle, which in all cases of mitral insufficiency presents itself sooner or later, although at first the double outlet for the blood from the ventricle would seem to demand less strength of the left ventricle. The right ventricle, however, in its hypertrophied state, delivers more blood through the lungs to the left ventricle, which demands more power to drive it on, hypertrophy results, and thus compensation is for a time longer maintained. Sooner or later the right ventricle dilates, the tricuspid valve becomes insufficient, the blood regurgitates into the right auricle and thence into the great veins of the neck. The valves of these ultimately yield, the jugular pulse appears, and the general venous system is engorged.

Incompetency of the cardiac valves is often brought about by dilatation of the ventricles and the great vessels leading from the heart, the valve leaflets themselves remaining intact. Such *relative insufficiency* affects most frequently the auriculo-ventricular valves, and, as a consequence, the latter are not "sufficient" to stretch across their respective orifices and close them. Less commonly the semilunar valves are similarly deficient; more frequently the aortic in dilatation of the aorta; and more rarely also the pulmonary valve when that vessel is dilated. It should be said of auriculo-ventricular insufficiency of this kind that it is found more frequently in the autopsy-room than recognized clinically, for it does not always cause a murmur.

Etiology.—Endocarditis, acute or chronic, is the most frequent initial cause of mitral insufficiency.

Symptoms.—Often there are no symptoms, because for a considerable length of time compensation keeps pace with the development of the disease unless the latter be sudden, as by rupture of a valve leaflet. The first thing noticeable is usually *shortness of breath* on exertion, the so-called *cardiac asthma*. With this is soon associated *palpitation*, or "beating" of the heart, which increases and abates *pari passu* with the dyspnea. Next is *irregularity of the heart's action*. This is the beginning of waning compensation, of which the immediate result is congestion of the lungs. Dyspnea is now permanent. Thence the engorgement extends to the right ventricle and venous side of the circulation, the pressure in the arteries being proportionately less. The lung engorgement invites frequent attacks of bronchitis, excites *cough* and increases dyspnea. *Orthopnea* is frequent at this stage, and the patient can only rest sitting in a chair. There is sometimes *blood-stained expectoration*, in which may be found alveolar epithelium dotted with pigment granules.

Along with this, or before it, the *liver becomes congested*, enlarged, and tender; the mucous membrane of the stomach also becomes congested, causing *nausea* and *indigestion*. The hepatic enlargement is sometimes very great, and I have known it to be mistaken for cancer of the organ. The liver is often the seat of pulsation, and as often a jugular pulse is seen. Both signs are pathognomonic of mitral regurgitation. Later, this enlarged liver may return to its normal state or contract still further, constituting the so-called *red atrophy*. In advanced stages the kidneys also become passively congested, the urine is scanty and its specific gravity high, while there are copious deposits of urates. It contains a small quantity of albumin and there may be hyaline tube-casts, rarely even a few blood discs. As a secondary result of hepatic engorgement only there may also be enlargement of the spleen.

Concurrent, or succeeding on failing compensation, comes *edema* or *dropsy*, the direct result of venous engorgement and the filtration of the liquid elements of the blood into the subcutaneous connective tissue of the body—first of the feet and legs, then of the trunk, face, and upper extremities, and, finally, into the pleural and peritoneal cavities, causing various degrees of inconvenience. Effusion into the pleural sacs may occur before there is any tendency to dropsy elsewhere. Allusion has been made to the studies of J. Dutton Steele on this subject on page 548. Dr. Steele does not, of course, deny the effect of concurrent conditions, such as diaphragmatic pleurisy, hepatitis, and the like.

Nose-bleed is a symptom sometimes seen in this disease. It is a natural result of the venous congestion.

Physical Signs.—*Inspection* discovers the apex-beat to the left of its normal position in the fifth interspace, or perhaps a little lower down. It may be in the line of the nipple or even beyond it, more forcible and diffuse than in health. The outward dislocation of the apex-beat is due to the enlargement of the two ventricles. In thin persons an auricular impulse may be seen to the left of the pulmonic area in the *second interspace*, and may be presystolic and active for the auricle—that is, produced when the auricle contracts; or systolic and passive for the auricle—that is, caused by a filling of the auricle by regurgitation from the ventricle during the latter's systole. In young persons a bulging precordium may be looked for in the second and third interspaces to the left of the sternum; also to the left of the lower part of the sternum from hypertrophy of the right ventricle. In advanced stages there is a jugular pulse, which is also pathognomonic of tricuspid regurgitation.

On *palpation* the apex-beat is found more forcible than normal, at least while compensation is maintained, and there may be a pulsation near the ensiform cartilage, caused by the *systole of the enlarged right ventricle*. As compensation wanes the apex-beat becomes weaker and irregular. Sometimes an intermittent *systolic thrill* is felt in the *fourth interspace* in the left mammillary line. Very rarely is there a systolic thrill at the apex.

The radial pulse in the early stage is comparatively unaltered. Later, it becomes frequent and irregular in volume. Appended (Fig. 53) is a sphygmogram of the pulse in advanced mitral insufficiency. It is of the type of the *pulsus parvus irregularis*.

Percussion finds enlargement of, both the relative and absolute areas of dullness, upward in the direction of the left auricle, downward to the left and also to the right, the right border of the heart extending at times beyond the right border of the sternum.

Auscultation recognizes a systolic murmur in the mitral area, conducted with various degrees of loudness into the left axilla and under the angle of the scapula. This direction of its conduction is the distinctive feature of this murmur. It is usually soft, but occasionally rough, more rarely musical. Richard C. Cabot says that musical murmurs are heard more frequently at the

Fig. 53.—Tracing of Pulse of Mitral Insufficiency.

mitral valve in regurgitation than at any other valve. A fading mitral systolic murmur generally means failing compensation, and when compensation is completely gone it is substituted by incomplete valvular sounds, great irregularity, gallop rhythm, labored breathing, and all the signs of pulmonary congestion. It is also sometimes heard distinctly to the left of the pulmonic cartilage, and rarely over the entire precordium. Not always loud enough to be easily heard, it may be brought out by exertion on the part of the patient.

The second sound of the heart is heard sharply accentuated at the pulmonary area until the tricuspid valve fails, when the accentuation fades away. The aortic second sound is less strong, corresponding with the smaller degree of hypertrophy of the left ventricle.

Differential Diagnosis.—The mitral regurgitation murmur is not usually difficult of recognition through the features which have been described. A functional murmur is rarely heard at the apex. Should it happen that it is, it will not be conducted as is the organic mitral systolic murmur, and it is not heard behind and below the angle of the scapula. Aortic roughening produces a murmur heard at the same time as the mitral systolic, and may also be propagated to the apex, but the position of greatest intensity is the second interspace to the right of the sternum and the murmur is transmitted loudly into the great vessels of the neck, which is never the case with the mitral systolic murmur. The tricuspid systolic murmur occurs at the same time, but its point of greatest intensity is at the ensiform cartilage; it is not commonly a loud murmur and is more apt to be observed by the mitral regurgitant murmur than it is likely to obscure the latter.

MITRAL STENOSIS.

Occurrence and Mechanism.—This lesion occurs as an uncombined or simple form of valvular disease in young persons, especially women, but is more commonly combined with mitral insufficiency. Seventy-six per cent. of all cases are said to occur in the female sex. In the simple form the orifice is stenosed, and the blood is restrained from passing freely into the left ventricle. It is backed into the left auricle, the lungs, right ventricle, and general venous circulation, but the left ventricle is not hypertrophied in simple mitral obstruction because no extra muscular demand is made on it, while hypertrophy of the left auricle is one of its most characteristic signs. Theoretically, the left ventricle should even atrophy from diminished function. Practically this does not occur, but the absence of the enlargement is of great diagnostic value. Excellent compensation is often maintained in mitral stenosis for many years.

Pure stenosis without regurgitation is possible if the mitral valve leaflets are fused without retraction, so as to form the funnel-shaped opening already described. In these cases a postmortem demonstration of insufficiency by means of the hydrostatic test is scarcely possible. Less frequently the mitral orifice viewed from above is a mere slit,—Corrigan's buttonhole contraction,—straight or slightly crescentic, in a smooth septum formed by fusion and contraction of the valve leaflets and tendinous cords. In some cases calcareous infiltration is added, and in a few rare instances uratic deposits are found. The ratio of buttonhole mitral stenosis to the funnel-shaped orifice varies with different observers—1 to 10 by A. E. Sansom, 1 to 13 by Hayden, 1 to 46 by Hilton Fagge.

Etiology.—Most frequently mitral stenosis is the result of endocarditis, acute or chronic, but it may in rare cases be congenital. In these cases, of which a number have been collected by Bedford Fenwick, the stenosis is secondary to narrowing of the tricuspid orifice, thus explained: A small quantity only of blood being allowed to pass into the right ventricle and lungs, a diminished supply is sent to the left heart, whence both its cavities and orifices are reduced in size. *No functional disorder can cause mitral stenosis.*

Symptoms.—These, often delayed by compensation, as in mitral insufficiency, are the same as in that lesion. In consequence of this commonness of symptoms the diagnosis of mitral stenosis is based largely on the physical signs.

Physical Signs.—Mitral stenosis may exist for many years without giving rise to physical signs. *Inspection* consistently with what would be expected in absence of hypertrophy of the left ventricle, recognizes little or no displacement of the apex in pure stenosis. If there is any, it is due to the hypertrophy of the right ventricle, which pushes the apex toward the left rather than downward and to the left. Nor is the true apex-beat increased in force, though there may be strong epigastric pulsation because of hypertrophy of the right ventricle, and in persons with thin chest-walls there may be an impulse in the *third and fourth interspaces* to the left of the sternum while compensation is maintained. A left auricular impulse, presystolic, may be noted in the second interspace to the left of the sternum, for the same reason as in mitral regurgitation. A *jugular pulse* may also be present if there is tricuspid regurgitation. A bulging precordium is possible only from great enlargement of the right ventricle and is not often seen. In children the lower sternum and fifth and sixth left costal cartilages may be prominent from this cause.

Palpation discerns that the apex-beat is without undue force, but it may be diffuse, and an impulse may be felt in the epigastrium, the situation of the apex of the right ventricle. The most marked feature recognized by palpation is the *presystolic thrill* at the apex, differing in this respect from the rare systolic thrill of mitral insufficiency. It is usually best felt in the fourth or fifth interspace, within the nipple-line. It is similar in rhythm to the presystolic murmur, but may be present without it. It is often absent. It is pathognomonic of mitral stenosis.

In moderate degrees of stenosis the *pulse* is not altered; in high degrees it is small, from want of blood and left ventricular power. Irregularity, like that of mitral regurgitation, is characteristic of advanced stages. Two tracings from cases of mitral stenosis are introduced in the text.

Percussion recognizes cardiac enlargement in the direction of the left auricle and right ventricle, but not of the left ventricle in pure mitral stenosis.

Auscultation may not recognize a murmur in every case of mitral stenosis because of the feebleness of the auricular contraction, especially toward the end of life, when compensation has failed and there is not the force of contraction sufficient to throw the blood stream into audible vibration. Most characteristic is the abruptly terminating *presystolic* murmur, confined for the most part to the mitral area to the inner side of the apex-beat, though it may be conveyed upward, and it is even heard posteriorly, though rarely. It is true that the presystolic murmur is heard in atypical situations, especially in the axilla and below the angle of the scapula, more frequently than has commonly been supposed.*

The *presystolic murmur* of mitral stenosis is a diastolic murmur occurring at the end of diastole of the ventricle, because it is at this time that the auricular systole takes place, giving the propulsive force necessary to produce the audible vibration. It is a loud, rough, vibratory murmur terminating suddenly with the first sound, sharp and ringing and coincident with the presystolic thrill. The murmur terminates with the impulse, and as the two are not always easily separable, the former is commonly more readily distinguished by its qualities than by its time. It is often followed by a "thumping" first sound, which, in consequence of this character, is sometimes mistaken for a second sound. As the disease advances it may occupy the entire period of diastole. In such cases there is sometimes a short pause between the beginning or diastolic part and the terminal or presystolic part of the murmur. In the last stage the murmur may disappear altogether, leaving only the snapping first sound.

Differential Diagnosis.—The murmur of mitral stenosis ought not to be confounded with the murmur of aortic regurgitation, for the latter is heard loudest in a different situation, but moreover there is enormous hypertrophy of the left ventricle, which is wanting in mitral stenosis. The time of tricuspid stenosis is identical with that of mitral stenosis, but it is heard in a different part of the precordium—in the epigastrium. Tricuspid stenosis is, however, a very rare lesion. Much more reasonably might the murmur of mitral stenosis be confounded with the so-called *Flint murmur*. This mur-

Fig. 54.—Tracing of Pulse in Mitral Stenosis.

mur is heard at the apex, at the same site as the presystolic, and may be similar in quality. It occurs in high degrees of dilatation of the ventricle, and is due to the fact, according to the late Austin Flint, Sr., that in such dilatation the mitral leaflets cannot, during diastole, be kept back against the ventricular wall, but remain in the blood current, throwing the latter into audible vibration. It may be said of the Flint murmur that it is never as intense as the mitral presystolic murmur. Otherwise the acoustic qualities are similar. The snapping first sound and systolic shock are also apt to be

* See an excellent, well-illustrated paper on this subject by J. P. C. Griffith in the "Transactions of the Association of American Physicians," 1895.

modified or absent. But the other signs of aortic regurgitation most help us to a diagnosis.

A rumbling sound succeeding a pericarditis in children, referred to especially by Broadbent and Rosenbach, has occasioned error, but this, too, is said to be unaccompanied by accentuation of the first sound at the apex. It is a transient murmur often succeeded by recovery.

These sources of error are well illustrated by the observations of Phear,* who investigated 46 cases of presystolic murmur in which no mitral lesion was found at autopsy. In 17 of these there was aortic regurgitation; in 20 of these there was adherent pericardium; in 9 nothing more than dilatation of the left ventricle was found. In none was the snapping first sound, so common in mitral stenosis, recorded during life.

Not infrequently the presystolic murmur is associated with a mitral systolic or regurgitant murmur, usually soft and not very loud, though sometimes it is distinct and is well transmitted into the axilla.

The pulse is small, as would be expected from the small volume of blood ejected from the ventricle, but may be quite regular, as seen in the sphygmograms. More frequently it is irregular. Sometimes there is a rhythmical failure of an alternate heart-beat to reach the wrist, while the sphygmogram will show a small rise between two higher ones constituting the *pulsus bigeminus*.

On account of the difficulties mentioned, while the presystolic murmur is a valuable sign of mitral stenosis, it should not be alone relied upon for diagnosis, but should be taken in connection with other signs. Tricuspid stenosis may be associated with mitral stenosis or insufficiency, or both. With the loss of compensation the presystolic murmur disappears together with the thrill, and there remains only the sharp, ringing normal first sound.

Accentuation of the second sound is marked, but confined to the pulmonary area, because there is no hypertrophy of the left ventricle. The *second sound* may also be *duplicated*, because of the want of synchronousness in the closure of the aortic and the pulmonary valves. Dr. Sansom regards this reduplication as only a seeming one of the second sound. He regards it rather as the normal second sound followed by another sound due to a sudden tension of the mitral valve itself. He also says it occurs in at least one-third of all cases of mitral stenosis, and is rare in other cardiac conditions. The accentuation of the pulmonary second sound also disappears with the enfeebling of the contraction of the right ventricle.

In slight degrees of mitral stenosis the second sound is heard at the apex, but as the lesion becomes more serious the second sound becomes fainter and eventually inaudible, though markedly accentuated in the pulmonic area.

The physical signs of mitral stenosis are more changeable and fleeting than those of any other valvular disease of the heart.

Dr. Sansom lays great stress on the evidence of the cardiograph in the diagnosis of mitral stenosis, which enables one to judge of the relative length of systole and diastole. In stenosis the diastole may be greatly prolonged, or the diastolic intervals vary greatly in duration. In mitral regurgitation, on the other hand, a short interval only separates the systoles.

Patients with mitral stenosis are subject to attacks of recurring valvulitis, with consequent embolism in different parts of the body. Embolism is a frequent complication of mitral stenosis. Pulmonary tuberculosis, quite

* "Lancet," September 21, 1895.

infrequently associated with valvular heart disease, is found more often in association with mitral stenosis than any other form.

MITRAL INSUFFICIENCY AND STENOSIS.

Occurrence.—More common than mitral stenosis as an uncombined lesion is stenosis associated with insufficiency, in which case we have the double mitral murmur, sometimes with difficulty divisible into its two parts. Extreme irregularity of rhythm and pulse, with frequency and smallness of the latter, conspicuous thrill, marked right-sided hypertrophy, and sharply accentuated pulmonic sound are characteristic of advanced stages. The presence of hypertrophy of the left ventricle points to associated mitral insufficiency and stenosis. Whence this combined lesion exists, mitral insufficiency is said to usually precede.

AORTIC INSUFFICIENCY OR INCOMPETENCY.

Occurrence and Mechanism.—By aortic insufficiency is meant an abnormal dilatation of the aortic orifice. This is the most serious and irremediable of the valvular diseases of the heart commonly met. Next in frequency to mitral incompetency, much more frequent than aortic stenosis, with which it more often coexists, it is a disease of men rather than women, commonly adults at or before middle life. The width of the aortic orifice increases from birth to old age, while the valve cusps tend to shrivel, so that conditions favorable to incompetency coexist. It includes 30 to 50 per cent. of all cases of chronic valvular disease. It is more frequently associated with arterial sclerosis and less frequently the result of rheumatic endocarditis, though it may be thus caused. It is the lesion most frequently followed by sudden death. When it exists, the aortic valves are incompetent to close the aortic orifice, either on account of the large size of the latter or of disease of the valve segments themselves, and the blood flows backward into the left ventricle during diastole. The ventricle, seeking to restore the balance, redoubles its energy and hypertrophies. The blood is thus driven into the aorta with great force, swelling the arteries to an extreme fullness, which, however, falls promptly away, because of the backward flow into the ventricle at the same time with the forward movement into arteries and capillaries. This sudden falling away of the pulse, from extreme distention to collapse, is very characteristic of this form of valvular disease, and is called the "trip-hammer" or "water-hammer" pulse, also Corrigan pulse. To the casual observer it may even be visible in the exposed arteries, such as the carotid, temporal, and radial, while the aortic beat, ordinarily beyond reach in the suprasternal notch, may be felt in this situation.

The abrupt jerking impulse with sudden recoil is easily recognized by the finger on the pulse, which, however, fails to find the pulse as strong and hard as would be expected from its appearance. On the other hand, it is soft and receding. It is commonly regular. A tracing of this pulse is seen in Figure 55. It is the typical *pulsus celer et altus*. A frequent and irregular pulse is much more serious in aortic valve disease than in mitral disease. *Sclerotic changes* in the *arterial walls* are not uncommon in aortic incompetency.

The product of this defect is the largest heart met in morbid anatomy, the left auricle and right ventricle often sharing in the enlargement. From its size the heart is called the *bovine heart*. It may weigh as much as thirty-five ounces (1050 gm.), and has attained a weight of fifty ounces (1500 gm.) or more. The cavities are enlarged and the walls are thickened, so that it furnishes an instance of eccentric hypertrophy. There may be ultimate dilatation of the arch of the aorta from the constant pounding of the blood against it in systole, while the carotids may be seen throbbing in the throat.

The gradual enlargement of the ventricle may ultimately cause the mitral valve to yield. Compensation is still maintained for a time by hypertrophy of the left auricle, which also yields after a time, becoming dilated and allowing the blood to engorge the lung. Hypertrophy of the right ventricle then comes to the rescue for a time. Sooner or later it, too, yields, dilates, the

Fig. 55.—Tracings of Pulse of Aortic Regurgitation.

tricuspid valve weakens, and finally gives way, allowing the blood to flow back into the venous side of the circulation, producing engorgement of the liver, stomach, kidneys, general dropsy—the train of symptoms described under mitral regurgitation.

Etiology.—Causes of insufficiency in addition to those considered under the general etiology of valvular disease are congenital malformations, including fusion of two leaflets, commonly those behind which the coronary arteries come off. Such fused leaflets are especially prone to valvulitis and its consequences. Aortic insufficiency is quite often caused by dilatation and aneurysm of the ascending aorta, giving rise to *relative* insufficiency.

Symptoms.—Like all other forms of valvular heart disease, aortic incompetency may be compensated for a long time, and elude detection for a corresponding time. Indeed, full compensation is said by some to be most usual in this form of valvular disease. Both *dropsy* and *dyspnea* are characteristically *absent* until compensation ceases, which is never the case until the mitral valve begins to yield. Then, however, both appear and may be very distressing. An especially frequent symptom is *dizziness* with *faintness*, particularly on rising quickly. *Palpitation* ensues on slight exertion, and this effect is in marked contrast to the comfort of the patient when quiet, when the pulse may be slow and breathing regular. In advanced cases, on the other hand, the patient complains of a constant “*beating*” or pulsation all over the body, especially in the head, which is exceedingly unpleasant.

The patient is very apt to be *troubled in his sleep* and to dream, probably because of disturbed circulation in the brain. Even permanent mental symptoms may result from this cause, including *insanity* and *suicidal tendency*. Lesser degrees are *irritability* and *peevishness*, though these are not confined to this form of heart disease. *Precordial pain*, present also in stenosis, is frequent in this form of valvular disease. It may be a dull ache with a sense of constriction of the chest, or sharp and radiating down the arms, particularly the left, as in *angina pectoris*, which condition itself is also common. With the yielding of the mitral valve and loss of compensation come the symptoms of mitral disease already described.

As previously stated, this is the form of valvular disease in which *sudden death* is most frequent. It has overtaken many a victim in the course of his daily vocation and without warning, though it is most apt to be induced by some slight overexertion or mental excitement. The cause of such sudden death is probably interruption of the circulation in the coronary arteries. This may be brought about in one of two ways. These arteries, in common with others, are especially disposed to endarteritis and resulting sclerosis and atheroma, a condition which constantly invites thrombosis and obstruction to the circulation; or it may be due to embarrassed circulation in these vessels, caused by the aortic regurgitation, for even if the blood enters the coronary arteries during systole, it must still receive in health some further supply in the recoil of the blood on the closed semilunar valves, which cannot take place when the valves are incompetent. On this variety, too, supervenes not infrequently acute infectious endocarditis of the grave type, with the train of symptoms and the sequelæ described. Embolism in various organs is also a complication independent of the acute involvement.

Physical Signs.—*Inspection* often discerns the prominent left precordium, with the apex-beat lowered and to the left, and the visible pulsation far beyond the normal situation of the apex, all confirmed by *palpation*. *Palpation* also recognizes at times a diastolic thrill over the base, in the carotids and subclavians, and sometimes in the aorta at the suprasternal notch. This is, however, much rarer in aortic regurgitation than the systolic thrill in stenosis. The Corrigan pulse may also be felt, but is much more strikingly manifested in the sphygmogram. A *capillary pulse* is also sometimes demonstrable in the skin and mucous membrane. This may be observed by drawing a pencil lightly across the skin of the cheek or forehead; and on the mucous membrane of the everted lower lip by pressing a glass microscope slide against it. It may often be well studied around the lunula of the fingernail. Pulsation in the retinal arteries may be recognized by the ophthalmoscope. Pulsation may even be seen in the uvula as originally pointed out by F. Müller in 1889, by Schlesinger* the next year and recently by David Riesman.†

Percussion discloses increased dullness to the left and downward, and also, sometimes in advanced cases, upward to the left of the sternum, owing to hypertrophy of the left auricle, as well as to the enlargement of the ventricle upward.

Auscultation recognizes a diastolic murmur, long, loud, and blowing in quality, usually harsher than the aortic obstructive murmur. It may or may not replace the second sound of the heart. It is well heard in the aortic area, but its seat of maximum intensity is commonly to the left of the second inter-

* "Wiener klin. Wochenschrift," October 4, 1900.

† "American Medicine," June 15, 1901.

space, near the midsternum, sometimes as low as the fourth left costal cartilage, and even at the ensiform cartilage. The murmur is naturally transmitted downward toward the ensiform cartilage or along the left edge of the sternum. Hence it may be mistaken for the murmur of tricuspid disease, but this, be it remembered, is unaccompanied by hypertrophy of the left ventricle. It is sometimes also well conducted toward the apex which is in the direction of the regurgitating column, but it is not conducted in the direction of the great vessels of the neck, at least with any loudness. In this condition also occurs the Flint murmur, described under mitral stenosis. This murmur is additional to the distinctive diastolic murmur (see p. 580). *The aortic regurgitant murmur is probably the most widely conducted of all cardiac murmurs.*

Auscultation of the vessels furnishes interesting information in aortic insufficiency. It is well known that if the stethoscope be placed as lightly as possible over the carotid artery of a healthy person, two sounds are usually audible, corresponding to the expansion and contraction of the artery. Of these the latter is simply the second aortic sound conducted into the carotid. It is probable also that the first sound corresponding with the arterial expansion is produced by vibrations of the arterial wall induced by the blood driven into it from the ventricle. The second arterial sound is greatly diminished in intensity or even absent in aortic incompetency, since the valve remains open. The aortic diastolic murmur is sometimes faintly transmitted into the carotid, while a short, rough, systolic murmur is sometimes heard in the same vessel. A valvular sound may also be heard in smaller arteries, such as the femoral, the brachial, and often the radial, the ulnar, and even the palmar arch and dorsalis pedis, by pressing lightly with the stethoscope, rendered more intense by strong pressure. Then there is *Traube's double sound*, in the femoral and popliteal arteries quite often heard. The sounds are such that the two follow each other closely, so that the first seems preparatory to the second, or they are separated by a longer interval, like the two sounds of the heart. No indisputable explanation of these sounds has been suggested. The first femoral sound is ascribed to a sudden filling of the unusually empty artery, and Traube explained the first of his sounds in this way, while he explained the second by sudden relaxation of this tension. Friedreich pointed out that a similar double sound could be heard in the femoral *vein* in tricuspid insufficiency, which he ascribed to tension of the valves of the vein. It is claimed that the double sound is heard in other diseases of the heart, especially mitral stenosis, and even in aneurysm, but it is acknowledged to be most frequent in aortic incompetency. Finally, there is *Duroziez's sign*, a murmur produced by pressure with the stethoscope upon the femoral artery, sometimes heard in aortic insufficiency. Duroziez's sign will be more easily understood when it is remembered that a murmur may be produced by pressure with the stethoscope on any artery of the caliber of the carotid. The murmur occurs during the expansion or diastole. During the collapse or systole of the artery, on the other hand, no murmur can be thus produced in health. In aortic regurgitation, however, this is possible, and it is the second murmur thus produced which is Duroziez's sign. It is said that this sign dies out as compensation fails. T. Clifford Allbutt does not consider Duroziez's sign peculiar to aortic regurgitation, though Vierordt says it is. A right degree of pressure, to be determined by practice, is necessary, and the artery on which it is obtained is usually the femoral.

AORTIC STENOSIS.

Occurrence and Mechanism.—By aortic stenosis is meant a narrowing of the aortic orifice. Pure and uncomplicated aortic stenosis is probably the rarest of the valvular lesions. Writers have been led into error because the presence of an aortic systolic murmur has been interpreted as meaning stenosis, where it has been produced by simple roughening of the valves or beyond them. Richard C. Cabot says that out of 250 autopsies made at the Massachusetts General Hospital, there was not one of uncomplicated aortic stenosis. Stenosis is said to be relative when there is a normal orifice while the aorta is dilated beyond it. It occurs in older persons, and the older the person, the more likely are there to be calcareous deposits causing it. It may be congenital. When uncombined with insufficiency, it is the least dangerous of the various forms of valvular disease. The narrowed orifice prevents the free discharge of blood from the left ventricle into the aorta. The ventricle attempts to overcome this, and its walls hypertrophy in proportion to the degree of resistance, and often for a long time compensate for the obstruction—until dilatation occurs, when the danger really begins. The hypertrophy thus induced, usually of the simple form, is only second in degree to that produced by incompetency.

Symptoms.—The symptoms of aortic stenosis may be long deferred, so long as compensation is maintained, and when they do occur, they are usually those of a deficient supply of blood to the brain and heart itself—viz., *dizziness* and *fainting*. Succeeding exertion there is apt to be a *sense of constriction* or *oppression* and even *pain* in the precordium, which may develop into the severe pain of a true angina pectoris.

Physical Signs.—*Inspection* and *palpation* recognize usually a forcible apex-beat outside of its normal site, and at varying distances, in accordance with the degree of hypertrophy. Some describe the apex-beat as without force and indistinct. Broadbent says it is “a well-defined and deliberate

Fig. 56.—Pulse-tracing of Aortic Stenosis.—Anacrotic Curve.

push of no great violence.” Palpation often perceives a *thrill* of great intensity with each beat of the heart, more marked when dilated hypertrophy is established. A bulging of the precordium may also be present, though less often than in incompetency.

The pulse is the *pulsus parvus et tardus*, slow in reaching its maximum volume, which is small. It is frequent, but regular, contrasting in the latter respect with the pulse of mitral disease. It is sometimes infrequent, *pulsus rarus*. Figure 56 is a sphygmogram.

Percussion elicits dullness downward and laterally toward the left, since, as a rule, the enlargement is confined to the left ventricle. There may, however, be slight enlargement upward to the left of the sternum if hypertrophy of the left auricle is added.

Auscultation discloses a systolic basic murmur, loudest at the aortic area,—second interspace at the right of the sternum,—conducted distinctly into the carotids, and even sometimes along the course of the aorta, behind and to the left of the vertebral column, into the popliteals and dorsal arteries

of the feet. It is not, however, confined to the aortic area, but may be heard over the entire precordium. It is usually rough, at least until compensation fails, but may be soft and musical. It may be heard even at a distance from the chest. It is late systolic, as a rule, following the apex-impulse, often at an appreciable interval. It is made louder by exercise. The *aortic factor* of the *second sound* is *very feeble*, or not at all heard, if the constriction be quite marked, because of the feeble recoil, the necessary result of the small amount of blood in the aorta. The first sound is normal, somewhat louder and more prolonged than natural, because of the powerful contraction of the left ventricle.

Roughness of the *aorta*, *dilatation*, and *narrowing* of the vessel, however caused, may also produce a systolic murmur; so may roughness within the ventricle in the course of the outgoing column of blood. But these causes have a less positive effect upon the substance of the heart—that is, do not produce as marked hypertrophy of the left ventricle. Nor do these causes interfere with the production of a normal second sound, except, perhaps, dilatation, which in that event is accompanied by an aortic regurgitant murmur. From this it follows that the important point to remember in diagnosis is that an aortic systolic murmur by no means always indicates aortic stenosis. So, also, anemic or hemic murmurs, which are always systolic and for the most part basic, may simulate aortic systolic murmurs but these occur in young, delicate persons of both sexes, are often intermittent and without other effect on the muscular heart, while they are also unaccompanied by thrill. There may be roughness, too, in the pulmonary artery, which can be localized to the left of the sternum.

Stenosis of the aortic orifice is very apt to be associated with insufficiency, the same rigidity and adhesion which prevent complete patulousness of the orifice preventing also complete closure.

Differential Diagnosis.—The signs which distinguish aortic stenosis from *aortic roughening* are not many. In aortic stenosis the pulse would naturally be small as contrasted with that of simple roughening or dilatation of the aorta. A systolic thrill is more characteristic of aortic stenosis. It may be felt at the base and apex, and rarely at the apex alone. From the last may be inferred that the cusp nearest the mitral leaflets is involved.

AORTIC STENOSIS AND INSUFFICIENCY.

Occurrence.—This double lesion is a comparatively frequent one; indeed, it is commonly regarded as the next in frequency after mitral insufficiency, and therefore more frequent than either aortic insufficiency or aortic stenosis alone. It occasions a double basic murmur, systolic and diastolic, and is also a grave condition, giving rise to the same dangers as aortic regurgitation, and the same enormous hypertrophy of the left ventricle.

Diagnosis.—The diagnosis of this condition requires special mention, because it not infrequently happens that it is mistaken for *aneurysm of the arch of the aorta*, which is associated with a similar double murmur of which the systolic element is due to the roughness of the aorta and aneurysmal walls, and of which the diastolic is a sign of relative insufficiency due to dilatation of the aorta. The distinctive differences between the two conditions will be given in treating aneurysm of the arch of the aorta.

TRICUSPID INSUFFICIENCY OR INCOMPETENCY.

Occurrence and Mechanism.—Tricuspid regurgitation as a primary condition is extremely rare, and, when present, is probably the result of an endocarditis during fetal life, endocarditis at this period being more prone to attack the right than the left side. Endocarditis involving the tricuspid valve may, however, also occur in children—according to Byrom Bramwell,* more commonly than has been supposed. Infectious or ulcerative endocarditis also affects the tricuspid valve—according to Osler, in 19 out of 238 cases. More frequently tricuspid regurgitation is the result of a *relative insufficiency*, one of the terminal events of mitral disease, the tricuspid orifice yielding with the dilatation of the right ventricle, which takes place sooner or later, consequent upon the resistance to the movement of the blood through the engorged lungs. It is also one of the possible sequelæ of emphysema of the lungs and long-standing fibroid phthisis or chronic bronchitis, succeeding, too, a primary hypertrophy of the right ventricle, due to these causes.

Thus, out of 405 autopsies at Guy's Hospital in which evidence of tricuspid regurgitation was found, 271, or two-thirds, resulted from mitral disease, 68 from myocardial degeneration, 55 from pulmonary disease, bronchitis, emphysema, and cirrhosis of the lung. The effects of tricuspid insufficiency growing out of the venous obstruction have been detailed on page 576.

Tricuspid insufficiency succeeding upon mitral insufficiency is not always accompanied by an audible murmur. It is evident that every case of mitral regurgitation associated with dropsy must be attended with tricuspid regurgitation. Very few of the cases above referred to had been diagnosed during life, and in all of them the valve was itself healthy, but insufficient to close the dilated orifice.

Symptoms.—These are those described when treating of mitral disease after the stage of tricuspid regurgitation has been reached, dropsy more or less general, engorgement of the stomach, liver, and kidneys, an enlarged, tender, pulsating liver, and a jugular pulse. The last two symptoms are regarded as pathognomonic.

Jugular pulse is often more forcible in the right than in the left jugular. There is also cyanosis, dyspnea, and pulmonary edema. The jugular pulse is systolic in time, and does not appear until the valves situated at the opening of the internal jugulars into the innominate veins yield. These give way first on the right side, because the course of the right innominate is straighter and communication is more direct. So long as the valve above the *bulbus jugularis* is closed, the pulse is confined to the bulb, but with the yielding of this valve the pulse becomes general throughout the vein. It is sometimes difficult to distinguish a true jugular pulse from the "physiological" or "false" jugular pulse, which may sometimes be seen in health and whenever the venous system is overfull. Pressure on the vein above the valves will cause the false pulse to disappear, while the true pulse, coming from the right ventricle, will remain. The physiological or false jugular pulse alternates with the ventricular systole and corresponds with the auricular systole, while the true jugular coincides with the systole of the ventricles.

Physical Signs.—In primary tricuspid disease with regurgitation, *in-*

* "Amer. Jour. Med. Sci.," April, 1886, p. 479.

spection and *palpation* reveal an apex-beat diffused toward the ensiform cartilage and the epigastrium. *Percussion* detects enlargement toward the right edge of the sternum, due to hypertrophy of the right ventricle, which occurs for the same reason as hypertrophy of the left ventricle in mitral insufficiency.

To *auscultation* the systolic murmur thus engendered is invariably feeble, and is heard almost solely in the tricuspid area, just above and to the left of the ensiform cartilage. Occasionally only is the second pulmonary sound accentuated. There should be no confounding of this murmur with that of aortic regurgitation conducted toward the same situation, but different in time, nor with that of mitral regurgitation heard at no great distance, for the reasons already given. To these must be added a difference in quality and pitch between the tricuspid and the mitral murmur, not always, however, manifest.

TRICUSPID STENOSIS.

Occurrence.—Tricuspid stenosis is a rarer condition, but it may be an acquired one in association with left-sided heart disease as the result of rheumatic endocarditis, and of unknown causes. Ninety per cent. of cases are associated with mitral stenosis. It is much more frequent in women, fully 80 per cent. of all cases being in women. As in endocarditis of the left side, there are thickening, adhesion, narrowing.

A presystolic tricuspid murmur pointing to stenosis, in a case observed by Gardner, was found due to a growth from the endocardium of the right auricle, so placed as to fall over the tricuspid orifice in the manner of a ball valve. Fred. C. Shattuck has met one instance of tricuspid stenosis with mitral stenosis and regurgitation, along with adherent pericardium, hepatic cirrhosis, and slightly granular kidney, as determined by autopsy. In this case there was a presystolic tricuspid murmur observed for three years before death.

Physical Signs.—Simple uncomplicated tricuspid stenosis would be recognized from the presence of a presystolic murmur and thrill, best heard in the tricuspid area, unaccompanied by hypertrophy of the right ventricle. When associated with left-sided heart disease, the diagnosis is seldom made, because the murmur is masked by the coincident mitral *presystolic murmur*. In a very few cases only is it confined to this valve. Frequently there is no murmur. Percussion shows dullness to the right of the sternum.

Congenital stenosis of the tricuspid orifice occurs, but is usually associated with defects of other valves, which early cause death.

Other symptoms are cyanosis of the face and lips and, in the later stages, extreme and obstinate dropsy.

PULMONARY INSUFFICIENCY OR INCOMPETENCY.

Occurrence.—Simple pulmonary regurgitation is rarely seen. It may, however, exist as a congenital defect (fusion of two segments), and the pulmonary valve has been found involved in ulcerative valvulitis.

Physical Signs.—It is easy from what has gone before to deduce the physical signs which are to be expected—a diastolic murmur heard in the pulmonary area, hypertrophy of the right ventricle, later jugular pulse, venous congestion, and cyanosis. The diastolic murmur may be confounded with

that of aortic insufficiency, but the latter is accompanied with hypertrophy of the left ventricle, with Corrigan pulse and capillary pulse. A few cases are related in which a diastolic murmur has been found associated with defects in the pulmonary valves—in one, warty, which might have been the result of infectious endocarditis. All others are congenital. Among them is aneurysmal dilatation. Such was a case reported to the Pathological Society of Philadelphia by Edward T. Bruen (see "Transactions" for 1883).

PULMONARY STENOSIS.

Occurrence.—The great majority of systolic murmurs heard at the pulmonary orifice are functional. Pulmonary stenosis, though very rare, may, however, exist, in which case it is far more likely to be congenital from arrested development, although intra-uterine endocarditis may also cause it. So, also, may infectious endocarditis, and in rare instances, atheroma. I well remember a case of malignant endocarditis with a pulmonary systolic murmur in which I was led from a correct diagnosis, because I thought that such murmurs are so invariably functional that it was scarcely worth while to consider the probability of an organic lesion. The autopsy disclosed a valvulitis of the pulmonary valve. Since then I have met other cases. The valve leaflets are apt to be fused. When the lesion is congenital, it is commonly associated with patency of the foramen of Botal or foramen ovale, together with imperfect ventricular septum and tricuspid stenosis.

Physical Signs.—Pulmonary stenosis should furnish a systolic murmur in the pulmonary area, to the left of the sternum. The murmur may even be heard behind, between the shoulders, and it may be rough. It is accompanied by hypertrophy of the right ventricle. There may be a basic thrill, as in aortic obstruction, but the pulse is uninfluenced. Compensation may be set up by means of a patulous foramen ovale, an open ductus arteriosus, or interventricular communication. The invariable presence of cyanosis due to venous obstruction and of attacks of dyspnea complete the picture and aid greatly in the diagnosis. Anemic murmurs at the same time and place are unaccompanied by cyanosis.

Walshe has described a case of death from thrombosis of the pulmonary artery in which he heard a pulmonary systolic murmur before the end came.

CONGENITAL DEFECTS.
